Departmental Committee on Graduate Students Program in Media Arts and Sciences Abstract

The lack of effective networking technologies for embedded microcontrollers is

inhibiting the emergence of smart objects and "Things That Think."

A practical communication infrastructure for Things That Think will require wire-

less network connections built directly into microcontroller chips. After showing

that digital processing, application languages, and wireless links are not the bottle-

neck, this thesis turns its attention to network designs. It presents architectures and

algorithms that implement self-organizing networks, requiring minimal pre-plan-

ning and maintenance.

The result is a radically new model for networks—embedded networks—designed

specifically to interconnect untethered embedded microcontrollers. The thesis cul-

minates in the design, implementation and evaluation of a hardware system that

tests and validates the approach.

CHAPTER 1 A Network on Every Chip

A trillion dumb chips connected into a hive mind is the hardware. The software that runs through it is the Network Economy. A planet of hyperlinked chips emits a ceaseless flow of small messages, cascading into the most nimble waves of sensibility. Every farm moisture sensor shoots up data, every weather satellite beams down digitized images, every cash register spits out bit streams, every hospital monitor trickles out numbers, every Web site tallies attention, every vehicle transmits its location code; all of this is sent swirling into the web. That tide of signals is the net.

—Kevin Kelly "New Rules for the New Economy" [Kelly 1997]

An unfulfilled promise

For years, visionaries have predicted that tiny computers will soon be woven into the everyday fabric of our lives and a world densely populated with "smart objects," giving rise to "Ubiquitous Computing," [Weiser 1991], "The Network Economy" [Kelly 1997], and "Things That Think" [Gershenfeld 1999]. These predictions have not yet been realized. Why not?

Processing power has become cheap and plentiful. Dollar for dollar, microcontrollers are a thousand times faster than a decade ago [Moravec 1998]. In the year 2000 alone, the total production of microcontrollers exceeded the world population [Tennenhouse 2000]. These tiny chips are being embedded into everyday objects—watches, pacemakers, smart cards, traffic lights, children's toys—at a prodigious rate. Clearly, available processing power is not the limiting factor.

Languages for microcontrollers have also proliferated. Mobile agents [Minar 1999], "thin clients" [emWare 2000], JINI [Sun 2000] and dozens of other computationally lightweight languages have been developed to support dedicated applica-

tions in embedded devices. Availability of these languages has not resulted in the predicted explosion of smart objects.

The steadily falling price of microcontrollers has resulted in situations where the cost of a single connector can exceed the cost of the microcontroller it connects¹. In the last few years, industry standards such as IrDA [IrDA 1998], IEEE 802.11 [IEEE 1999], and Bluetooth [Bluetooth 1999] have created wireless interconnect systems that are less expensive than their wired counterparts. Since these wireless technologies themselves make heavy use of semiconductor technologies, they enjoy progressively lower cost and increased communication rates per unit power.

Despite the availability of these essential ingredients—cheap, abundant processing; lithe application languages; and inexpensive wireless links—few everyday objects show any signs of increased intelligence.

Networking: the missing link

A typical embedded microcontroller works in relative isolation, unable to draw upon information or exert any influence beyond its immediate realm. For all its computing power, it is like a genius sequestered in a basement: smart and capable, but having neither sensory inputs to give it context nor the means to express what it knows. We are left with ubiquitous but senseless computing and billions of Things That Think which cannot relate.

Legacy networks are ill-suited for linking embedded microcontrollers Talk is cheap, at least among humans. But for the tiny embedded microcontrollers found in common objects, the cost of discourse remains relatively high. Today's digital networks were originally designed to interconnect mainframe and minicomputers and have been adapted, somewhat awkwardly, to connect PCs and lap-

A spot check of a popular electronics part supplier shows that in quantities of one hundred, the popular DB9 serial connector costs \$3.12, a microcontroller that processes one million instructions per second costs only \$0.94.

top computers. These legacy networks are ill-suited for embedded processors: they cost too much, they consume too much power, and they don't scale well to handle the hundreds and thousands of connections required in a world of Things That Think.

Embedded Networking

The lack of effective networking technologies for embedded microcontrollers is inhibiting the emergence of smart objects. What is required is a new model of networking—embedded networking—designed specifically to interconnect embedded microcontrollers.

A network must attain a critical mass if it is to be useful. As proposed by "Metcalfe's Law," the value of a network rises as the square of the number of devices connected. In a world where the number of embedded microcontrollers is growing exponentially, the only reliable way to arrive at and to maintain critical mass is to put the network connection directly on the chip.

The domain of Embedded Networking

Herb Simon points out that it is useful to consider a technology as "an 'interface'... between an 'inner' environment, the substance and organization of the artifact itself, and an 'outer' environment, the surroundings in which it operates." [Simon 1969]. Embedded Networks are built into embedded processors and provide communication links for specific applications in a relationship portrayed below in Figure 1. These contexts dictate the fundamental design requirements of embedded networks.

Embedded Networking is implemented on microcontrollers (its "inner environment") and interacts with dedicated applications (its "outer environment"). Each environment dictates constraints upon its design.

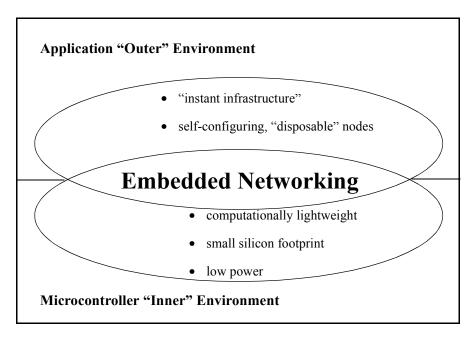

FIGURE 1. Context and constraints of embedded networking

Constraints imposed by the host

An Embedded Network node must not overly tax the microcontroller chip on which it is built. The host microcontroller on which the Embedded Network node is fabricated—its "inner environment"—imposes a set of constraints. The power of microcontrollers lies in their generality: a single microcontroller architecture is suitable for a broad range of applications. For embedded networking to be viable, it too must be adaptable to a broad range of applications. Since the embedded network system resides on the microcontroller chip itself, it must not impose a significant burden on the chip, giving rise to the following design principles:

LOW POWER CONSUMPTION

For an embedded network node to be an attractive candidate for integration onto a microcontroller, it should not exceed the power consumption of the microcontroller itself.

One of the consequences of Moore's Law—the proposition that the number of transistors per unit area of integrated circuit doubles every eighteen months—is that of reduced power. Smaller devices have lower parasitic capacitance, which in turn results in reduced switching currents. Microcontrollers now exceed 10⁹ instructions per second ("1 GIP") per watt, or "one MIP per milliwatt," allowing substantial computation to be powered by relatively small batteries.

Some of the more aggressive radio designs to date have yielded systems that consume approximately 4 nano Joules per transmitted bit [Carvey 1996]. With a continuous transmission at 100 KBits/second, these radios will consume 400 μ Watts—a figure on par with the power consumption of modern host microcontrollers.

SMALL SILICON FOOTPRINT

The manufacturing cost of silicon microcontroller chips is correlated to die size. More smaller chips can be packed onto a single silicon wafer, and smaller chips have higher yields. In order to keep costs low, the circuitry that implements embedded networking should account for a small percentage of the overall chip size. This favors networking algorithms with small routing tables and computational simplicity.

LOW COMPUTATIONAL OVERHEAD

Computing consumes power. Networking algorithms that require less computation will be suitable for wider range of applications, especially those that are limited by available power.

As of this writing, several processor families meet or exceed 1000 MIPs per Watt, including Intel's XScale based StrongARM, Hitachi SDH-4, Texas Instruments MSP430 and Toshiba TX19. The list is growing rapidly.

Constraints imposed by the application

The application—the "outer environment" of Embedded Networking—imposes a second set of design constraints³.

Things That Think will become woven into our everyday environment, standing ready to serve wherever and whenever we want them and fading into the background whenever we don't. The networks linking these devices will create their own invisible mesh of communication without pre-planning, intentional placement or maintenance. If a device demands our attention, it should be due to an application-specific imperative and not due to a failing of the network⁴.

The major design principals for Embedded Networking imposed by its Outer Environment can thus be summarized as follows:

INSTANT INFRASTRUCTURE

It is unreasonable to expect people to configure and administer a network of Things That Think. An Embedded Network must serve its users, not the other way around. This requires a network system that is created upon demand and automatically reconfigures itself as devices are added to or removed from the network.

SELF-CONFIGURING, "DISPOSABLE" NODES

Properly designed Things That Think will have networking built in, not added on, which will be reflected in their usage: devices will become integrated into a network simply by physically bringing then into the networking environment⁵. The

^{3.} In this setting, *application* means "the task to which the system is applied" as opposed to "software written in support of a task."

^{4.} In the terminology of philosopher Martin Heidegger, Embedded Networking should support devices that are "ready to hand" without causing them to become "present at hand."

network should support dynamic discovery and routing so that network services remain available as much as possible, even as devices go off-line or move.

The lifetime of a network connection will be the same as the lifetime of the object into which it is embedded. The day you dispose of an object, you dispose of the network connection without giving it a second thought.

CASUAL PLACEMENT

Conventional wireless networks are carefully planned with respect to location, usage patterns and density. By contrast, the quantity and density of an Embedded Network cannot generally be known beforehand. The design of an Embedded Network should support a broad range of possible device configurations, from the few to the many and from very sparse to very dense.

Contributions of this thesis

GRAD - GRADIENT ROUTING FOR AD HOC NETWORKS

Chapter 4 describes "GRAd," a decentralized, self-organizing, multi-hop network architecture that addresses many of the design issues outlined above. GRAd's routing algorithms offer dynamic discovery and routing, and are shown to be robust even in networks with a high degree of topological change. Its multi-hop approach offers significant savings in radio transmit power. The decentralized approach used by GRAd avoids the congestion of a single base station or access point, allowing it to support up to thousands of nodes. By allowing redundancy among relaying nodes, GRAd exhibits improved reliability over unreliable links. GRAd exploits a simplified Medium Access (MAC) layer to attain lower power per transmitted bit than other comparable networking algorithms. By storing only information about

Some applications may call for "imprinting" a device prior to its use, for example to establish ownership. See [Stajano 1999] for an excellent description of how this can be implemented.

routing endpoints, GRAd's routing tables stay relatively small, and its networking algorithms are computationally simple—both of these points work together to make GRAd ideal for direct implementation on embedded microcontrollers.

DISTRIBUTED SYNCHRONIZATION

While multi-hop routing can significantly reduce the power used for radio transmissions, it doesn't address the power used for reception, which has been shown to dominate the power budget of conventional self-organizing wireless networks [Wheeler 2000]. Chapter 5, "Distributed Synchronization," shows how nodes in a wireless network can synchronize to one another without depending on a centralized time base. Once synchronized, nodes can significantly reduce their power consumption by enabling their radio receivers at selected times.

STATISTICAL MEDIUM ACCESS

Because the placement of nodes in an embedded network are not generally preplanned, the network can experience a wide range of node density. Chapter 6, "Statistical Medium Access," explores the effects of variable density. It will be shown that nodes can use a technique of "statistical medium access," to maximize the likelihood of successful transmission in a crowded environment. The probability of success converges as 1/e for an arbitrary number of co-located nodes.

ARBORNET

Chapter 7 presents "ArborNet," a prototype implementation of an embedded network. Built from commercial off-the-shelf components, ArborNet employs the basic techniques developed by this thesis to implement a self-organizing, wireless sensor network.

The promise, revisited

An Embedded Network is a new paradigm in networking, and offers several benefits over conventional wireless networks.

- Instant Infrastructure—A node in an Embedded Network can join a network simply by bringing it within range of other nodes. This is important for creating "ad hoc" networks quickly on demand, such as in military and emergency applications. Embedded Networks are especially well suited for consumer applications, since new devices can be integrated into a network with minimal effort.
- Proxy Intelligence—A clock should know how to set itself. A child's toy should
 be able to recognize its owner's voice. No particular "intelligence" is required in
 the clock or toy when an Embedded Network links these devices to other computational services.
- Data Aggregation—Today's computers have been described as "deaf and blind" [Pentland 1998], sensorially deprived and unable to act sensibly. Embedded Networks can be used to gather crude data from hundreds or thousands of sources for distillation into high-quality information.
- Cheap Links—In many cases, the cost of physical links is a significant part of a
 total system budget. For example, a light switch costs only about \$2 for the
 switch itself, but the cost of conduit, copper wire, and installation time brings
 the installed cost to over \$70. In many cases, Embedded Network links offer
 inexpensive alternatives to wired connections.

What will happen?

What will happen when every embedded microcontroller comes equipped with its own wireless, self-organizing, scalable network connection? Answering this question is a bit like trying to anticipate the effects of the Internet a decade ago. It was widely believed that the Internet could make a large difference in the way we communicate, but few people could anticipate the depth and breadth of its effects.

So it is with embedded networking. While it may not be possible or practical to anticipate the specific manifestations of embedded networking, it is entirely reasonable to believe that the implications will be large. Some of the applications are easy to imagine:

- ArborNet—understanding the biosphere of the forest floor. A paper company
 owns thousands of acres of forest but, short of sending in survey crews, has little
 knowledge of the ecology and health of the forest. So they create a small "dart"
 with a tiny analysis lab in the tip and a radio link in the tail. Thousands of these
 darts are scattered from an airplane over the forest, forming a complete communication mesh that informs the company about drought, flood, or fire conditions.
- OmniSense—an office building on-line. Once every light switch, thermostat,
 door jamb and motion detector of a building are connected to a network, power
 and security systems can be precisely managed. Over time, the system can learn
 the patterns of usage, allowing it to anticipate ordinary events and to flag abnormal conditions.
- Vox Populi—an inter-village telephone system. Imagine a telephone system that is as easy to set up as handing out telephone handsets. There is no expensive base station—the telephones themselves become the network. And as a boon (or a bane) to the prevailing government, a system can be designed for which centralized control is neither necessary nor possible.
- GridKey—a solution to urban gridlock. Each street corner of a city has a simple sensor that detects the passage of cars. All of the sensors are networked together so analysts—both human and computer—can form a city-wide picture of traffic patterns, adjusting traffic signal timing and issuing advisories to reduce congestion. Individuals can access this information via mobile devices and plan their routes accordingly.

Perhaps the best way to learn about the implications of embedded networking is to build them. Herein lies the crux of this thesis.

CHAPTER 2 Precedents in Wireless Networks

Existing standards do not address the needs of Embedded Networks. In their quest to communicate further and faster, none yield networks that are simultaneously self-organizing, low-power and scalable. In the early 1970s, the Packet Radio Program, funded by the Advanced Research Projects Administration (ARPA), and Norm Abramson's AlohaNet laid the groundwork for wireless digital networks [Kleinrock 1987][Abramson 1985]. Since that time, wireless digital communication systems have grown both in range and capability. Satellite-based systems provide global wireless networks. Locally, high-speed wireless links are commonplace in today's office buildings.

Wireless Local Area Networks (WLANs) offer high speed communication over short distances. The popular 802.11 standard offers communication rates of 11 megabits per second over a range of 200 meters [IEEE 1999]. Wireless Wide Area Networks (WWANs) offer longer range at reduced bit rates, as exemplified by the UMTS standard with a bit rate of two megabits per second carried over cellular telephone networks [UMTS 2000].

BLESSED ARE THE MEEK...

Wireless LAN's are optimized for speed, wireless WAN's are optimized for distance. By contrast, the important attributes for embedded networks are neither speed nor distance, they are power and scalability at a low cost. When voice or image data need to be transmitted, current networks may be the most appropriate. However, for many everyday objects, communication rates on the order of bits per hour—not megabits per second, will suffice. Figure 2 highlights the natural home

of embedded networks: low bit-rate short-haul communications, an area left untouched by conventional wireless networks.

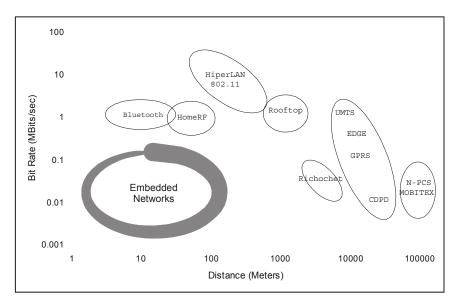

FIGURE 2. Distance versus bit rate for wireless standards

As established in Chapter I, a viable embedded network will have a multi-hop architecture with decentralized control. It will have dynamic routing and will also incorporate power conservation techniques in its core design. As shown in Table 1 below, in their quest to communicate further and faster, none of the existing standards simultaneously address all four of these attributes.

TABLE 1. Packet switched wireless networks

wireless standard	s standard attributes				
	Decentralized	Dynamic Routing	Multi-hop	Managed power	comments
Historical Systems

Legacy systems

ALOHANET

AlohaNet was developed in the 1970s by Norman Abramson and his colleagues, and is one of the earliest packet-switched wireless digital networks. It used ground-based radios transmitting on a single shared channel. While this architecture is not generally scalable—congestion increases with the number of nodes—AlohaNet and

its analysis spawned many other systems, including Ethernet and TDMA protocols for satellite communication.

PACKET RADIO

Packet Radio systems are among the earlier examples of multi-hop wireless communication systems¹. In 1972, the ARPA launched the Packet Radio Program, designed to develop robust communication systems for the battlefield. In the late 1970s, amateur radio operators developed "Terminal Node Controllers" (TNCs) to form digital links among meshes of ham radios. Since then, TNCs have evolved to support several forms of multi-hop communications, including static and dynamically discovered routing (ROSE and NET/ROM respectively).

Local Area Networks

Всиетоотн

Developed by an industry consortium, Bluetooth specifies a radio and access protocol. The radios are spread-spectrum in the 2.4GHz band, and will form ad-hoc "piconets" of up to eight devices. Within each piconet, one device is the local master and chooses a spreading code. Other devices within that piconet use the master for control and synchronization. One master may participate in multiple picnonets to form a "scatternet," but the specification does not support multi-hop communication.

802.11 WIRELESS LAN

IEEE 802.11 has been widely adopted as an industry standard for Wireless Local Area Networks. Links are specified as 2.4 GHz spread-spectrum transceivers using

To be fair, Packet Radio was hardly the first multi-hop wireless communication network: Napoleon's Optical Telegraph, built before the turn of the 19th century, predated packet radio by 170 years.

CSMA protocols. Channel data rate is as high as 11 MBits/sec. 802.11 works well for linking several dozen devices to a wired Access Point (base station), but will not scale well to higher densities.

802.11 also specifies an ad hoc mode, which provides point to point links at the expense of frame relay and power savings support.

HIPERLAN

Hiperlan/1 (High Performance European Radio Local Area Network) has been developed by ETSI (the European Telecommunications Standards Institute) as a second generation wireless local area network. It supports bit rates of 20 MBits/second at distances of up to 50 meters. The standard specifies the physical layer (PHY) and the Medium Access Layer (MAC), and while it admits the possibility of a multi-hop architecture, it does not specify how it should be implemented.

Hiperlan/2 is a new WLAN standard being developed at ETSI. It specifies channel bit rate of 54 MBit/second with intra-nodes distances up to 100 meters.

DECT

Development of the DECT (Digital Enhanced Cordless Telecommunications) specifications was started in the mid-1980s and finished in 1992 by ETSI. Originally developed as a standard for cordless telephones, the scope of DECT has been expanded to support general digital radio access. The current standard offers a base station architecture with wireless data links of 1.152MBits/second over a range of 100 meters. According to Ericsson, DECT permits the highest user densities of any cellular system, up to 100,000 nodes per square kilometer².

^{2.} See the online document http://www.ericsson.com/BN/dect2.html for more information.

HOMERF

The HomeRF Working Group is creating specifications for low-cost intra-home networking named SWAP (Shared Wireless Access Protocol). SWAP has adopted a hybrid approach, using 802.11 protocols to carry data and DECT protocols to carry voice. A SWAP network will support up to six voice conversations and up to 127 devices in each network.

As in 802.11 networks, a SWAP network can work in ad hoc mode, in which all devices have equal access to the network, and in managed mode, in which one central device coordinates the operations of the other nodes in the network.

Wide Area Networks

RICOCHET

Developed by Metricom Corporation of Los Gatos, CA, the Ricochet Network is one of the first commercial multi-hop wireless digital networks. A mesh of Network Radios, typically mounted on utility poles one to four kilometers apart, relay packets between Wireless Modems and wired Access Points. The first generation of Wireless Modems offered users a channel data rate of 28.8 kilobits per second; newer Modems provide 128 kilobits per second.

A Ricochet network is a multi-hop system, but not self-organizing: adding a new Network Radio to the mesh requires manually incorporating it into the network and setting up static routing to the nearest wired Access Point.

ROOFTOP

Rooftop Communications (recently purchased by Nokia) offers wireless networking products that form a multi-hop, dynamically routed mesh of terrestrial radios. Each radio runs in the 2.5 GHz ISM band, supports link rates of 1.6 MBits/second, and has a range of approximately three miles.

CDPD, UMTS, EDGE, GPRS

CDPD (Cellular Digital Packet Data), UMTS (Universal Mobile Telecommunication Systems), EDGE (Enhanced Data Rates for Global Evolution) and GPRS (General Packet Radio Service) are wireless systems that use cellular telephone networks to carry digital data. Data rates range from 19.2 kilobits per second (CDPD) to a predicted rate of 2 megabits per second (UMTS).

N-PCS, MOBITEX, ARDIS

N-PCS (Narrowband Personal Communication Services), MOBITEX and ARDIS (Advanced Radio Data Information Services) are essentially two-way pager systems. Low bit-rate data is transferred between individual mobile units and high power base stations. Data packets are usually of limited size, and data rates range between 8 and 24 kilobytes per second.

Other multi-hop protocols

MANET

The mobile ad-hoc network (MANET) working group is an effort within the IETF (Internet Engineering Task Force) to develop and evolve routing specifications for wireless ad-hoc networks containing "up to hundreds" of nodes. The working group has already published ten Internet Drafts for discussion and debate, and covers such topics as adaptive routing and quality of service.

A standard benchmark for MANET network protocols assumes that they are implemented using 802.11 wireless links running in point-to-point "ad hoc" mode. In this mode, individual neighbors must be known in order to achieve media access, and the three way handshake at each packet transfer increases latency. Power conservation is not possible as the receiver cannot be turned off.

OTHER PROTOCOLS

The last few years have seen many developments in ad hoc, multi-hop routing protocols. Active areas of research include data-directed routing for network efficiency, data aggregation to reduce network traffic and choosing cluster heads dynamically to reduce per-node power requirements [Intanagonwiwat 2000], [Heinzelman 2000]. These techniques show promise as important components of Embedded Networking systems.

What's missing?

Although existing wireless standards address a range of applications from low bit rate, long distance communication to high-bandwidth, short haul systems, none of them have the right mix of scalability, self-organization and low-power required as a basis for embedded networking. A re-thinking of the network is needed.

CHAPTER 3 Multi-hop Communications

Imagine you are at a party where the conversation flows as freely as the champagne. Suddenly, a guest picks up a bullhorn and shouts out in a booming voice to his friend on the opposite side of the room, asking for some more duck canape. The sound is deafening, and all other conversation comes to an abrupt stop.

The virtues of whispering

Many familiar wireless communication systems, including cellular telephones, two-way pagers and wireless LANs use a *single-hop* design: a central base station or access point maintains direct radio communication with each terminal node of the network. A single-hop system can be likened to that bullhorn: whenever the base station transmits, it precludes other communication within its area.

By contrast, in a *multi-hop* wireless network, each node transmits with reduced power, communicating with a set of neighboring nodes within a limited range. Those neighboring nodes in turn relay the message on behalf of the originator, and so on, until the message arrives at intended destination.

Multi-hop communication conserves transmitter power and increases system bandwidth. Multi-hop networks offer advantages over their single hop counterparts. By reducing the transmit range in each node, multi-hop networks offer substantial power savings. Multi-hop networks exploit spatial reuse, yielding higher effective bandwidth. And by reducing the overall levels of radio interference and noise, multi-hop networks can scale to handle more nodes than single-hop networks.

Single-hop and multi-hop: an idealized comparison

In a single-hop network, each radio transmits with sufficient power to reach its ultimate receiver without intervening relays. In a multi-hop system, each radio transmits with enough power to reach one or more neighboring nodes, which will in turn relay the message until it reaches its final destination.

A representation of single hop communication is shown in Figure 3.

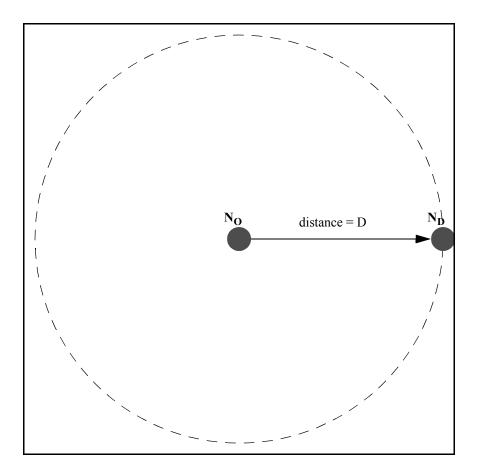

FIGURE 3. Single hop communications

In Figure 3, N_O is the originating node, N_D is the destination node, and the two nodes are separated by a distance D. The transmit power required to span a distance of D is defined to be P.

A multi-hop uses multiple relay stations to get the message from $N_{\rm O}$ to $N_{\rm D}$, as illustrated in Figure 4.

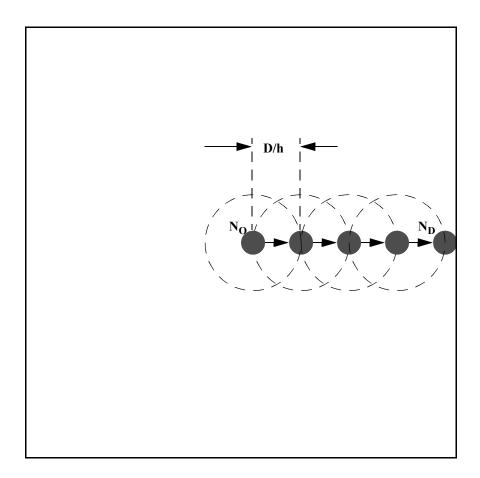

FIGURE 4. Multi-hop communications

Given a system that requires P units of power to transmit its message in a single hop and a path loss exponent of e, the per-node power required to send the message using h hops can be approximated by

$$P_n(h) = Ph^{-e} (EQ 1)$$

The system-wide transmit power is the sum over h hops, or

$$P_t(h) = Ph^{1-e} (EQ 2)$$

The path loss exponent in free space has a theoretical value of 2 for free space, but is typically cited as 4 or higher for office or urban environments.

Assume for the moment that each transmitter covers a perfectly circular area, and the distance covered by a single hop system is D. Assume that the transmitters in an h hop system are equally spaced at distance d = D/h. If each transmitter uses the minimum amount of power to reach the next receiver, the total area covered by the transmitters is given by

$$A_t(h) = \pi d^2 + (h-1)d^2\left(\frac{\pi}{2} - 1\right).$$
 (EQ 3)

If we define $k = \left(\frac{\pi}{2} - 1\right)$, Equation 3 can be written as:

$$A_t(h) = d^2hk + d^2(\pi - k)$$
. (EQ 4)

Substituting D/h for d in equation 4 yields:

$$A_t(h) = D^2 \left(\frac{k}{h} + \frac{(\pi - k)}{h^2}\right).$$
 (EQ 5)

Equation 5 tells us that the area covered by transmitters in a multi-hop system decreases roughly linearly with the number of hops.

Power savings

The rather idealized system using h hops has several advantages compared to its single-hop counterpart. The power required by each node is reduced by h^e , while

the total power consumed by the system is reduced by a factor of $h^{(e-1)}$ and the total area covered by transmission is reduced by a factor slightly larger than h.

As an example, assume a single hop system with a transmit distance of 100 meters in an office environment with a path loss exponent of 4. If we replace the single hop system with a 10 hop system, the transmit power per node is reduced by a factor of 10,000, the total system power is reduced by a factor of 1,000, and the area covered by the transmissions is reduced by approximately a factor of 12.

Figure 5 summarizes the relative transmit power for a variety of hops and path loss exponents.

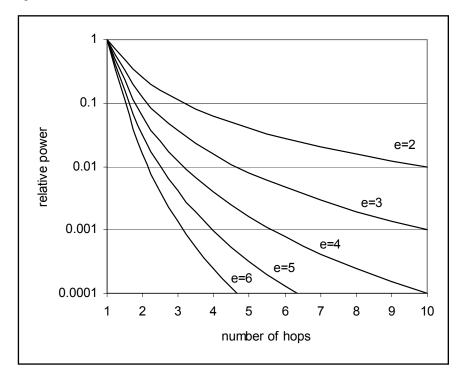

FIGURE 5. Per-node transmitter power (relative to single hop)

The power savings in a multi-hop network can be substantial. For example, in an environment with a path loss exponent of 4, transmitters in a five hop system require 0.0016 of the power compared to a single hop system.

Effects of non-uniform spacing

In the multi-hop scenario given above, relaying nodes are assumed to be evenly spaced between the source and the destination with the transmitter power set to the absolute minimum for reliable communication. In a practical embedded network, nodes will unevenly spaced, and some amount of redundancy and overlap must be expected if there is to be a continuous, reachable path between the originator and destination nodes.

The effect of overlap does not change the per-node transmitter power required, but it does increase the number of nodes involved in relaying the message and thus the total system-wide transmit power. Assuming a factor of N redundancy, the system-wide power of Equation 2 becomes:

$$P_t(h) = PNh^{1-e} (EQ 6)$$

Revisiting the example of a ten hop network with a path loss exponent of 4: if this network has a factor of five redundancy, this represents a factor of 200 reduction in total transmitted system power compared to its single-hop counterpart.

The effect of overlap is to increase the total system-wide power by a linear multiplier, while the savings in power through reduced distance are exponential. The net effect is that a multi-hop system conserves transmit power compared to a singlehop system, even when taking non-idealized spacing of nodes into account.

Summary

Multi-hop systems offer several advantages over single-hop systems.

REDUCED TRANSMITTER POWER

In a multi-hop system, the reduced distances between nodes allows the transmitter power to be reduced exponentially. For example, assuming a path loss exponent of 4, if the 100 meter range of an 802.11 wireless LAN node is reduced to ten meters, its transmitter power may be reduced by 40 db, or a factor of 10,000. This reduction in power results in longer battery life for individual nodes, and reduces the overall amount of clutter in the airwaves.

SPATIAL REUSE

In a single-hop system, transmissions from a base station to a single mobile node blanket the airwaves surrounding the base station. In a multi-hop system, the area covered by transmissions are localized by approximately a factor of h, where h is the number of hops. This permits simultaneous transmissions to take place in physically separate parts of the network—a technique sometimes referred to as *Spatial Division Multiple Access* (SDMA). Since the airwaves can support multiple transmissions, the effective bandwidth of the overall system increases.

MAPPING THE TOPOLOGY

In a single-hop system, a node is either within range of the base station or not: nothing is learned about the topology of the network. In a multi-hop system, the topology of the network can be acquired as the nodes converse with one another. This information can be used to establish optimal routes or physically locate a node. ¹

^{1.} Using a wireless network topology to model physical topography doesn't always work as well as one would hope, as will be shown in Chapter 7.

CHAPTER 4 GRAd: Gradient Routing for Ad Hoc Networks

This chapter presents *Gradient Routing* (GRAd), a novel approach to routing and control in wireless ad hoc networks. A GRAd network attains scalability through a *multi-hop* architecture: nodes that are not within range of one another can communicate by relaying messages through intermediate neighbors. Routing information is established on-demand and is updated opportunistically as messages are passed among nodes.

Unlike other ad hoc routing techniques, a node in a GRAd network does not single out a particular neighboring node to relay its message. Instead, it advertises its "cost" for delivering a message to a destination, and only those neighboring nodes that can deliver the message at a lower cost will participate in relaying the message. In this way, a message descends a loop-free "gradient" from originator to destination.

Since multiple neighbors can participate in the relaying of messages, GRAd maintains good connectivity in the face of frequently changing network topologies. A node does not need to know the identities of its neighbors and establishes routes on demand, making periodic "hello" beacons unnecessary and increasing the overall security of the network. Because GRAd does not use link to link handshakes, end-to-end latencies remain small.

The challenge

In any wireless ad hoc network, a major challenge lies in the design of routing and network control. Lacking any centralized point of control, nodes in an ad hoc network must cooperatively manage routing and medium access functions. Nodes may be mobile, creating continual changes in the network topology. Also, wireless links are not as robust as their wired counterparts; high bit error rates and packet losses are commonplace.

In the last decade, a number of ad hoc network protocols have been proposed. As an indicator of the amount of activity in this field, the Internet Engineering Task Force (IETF) recently formed the Mobile Ad Hoc Networking (MANET) working group to develop ad hoc protocol specifications and introduce them into the Internet Standards track [Macker 2000]. At this time, there are eight separate ad hoc routing protocols under consideration by the working group.

GRAd falls under the category of *on-demand* routing protocols, in which routes are established only when nodes wish to communicate with one another; no attempt is made to maintain state when there is no data to send.

In other on-demand routing protocols such as the *Ad Hoc On-Demand Distance Vector Routing* protocol (AODV) [Perkins 1999] and the *Dynamic Source Routing* protocol (DSR) [Johnson 1999], a node relays a message by sending to a particular neighboring node. The popular 802.11 MAC layer protocol uses "virtual carrier sensing" as part of its collision avoidance mechanism for such unicast transmissions [IEEE 1999], requiring a *request to send / clear to send* handshake (RTS/CTS) between each pair of wireless links. This exchange contributes to significant delays in the relaying of messages, resulting in long latencies.

By comparison, a node in a GRAd network makes no attempt to identify *which* of its neighbors is to relay a packet. Instead, it includes its "cost to destination" information in the packet and broadcasts it. Of all the nodes that receive the broadcast, only those that can deliver the packet at a lower cost will relay the message. In this way, the packet descends a loop-free "gradient" towards the ultimate destination.

Since each transmission is a local broadcast, GRAd does not (and in fact, cannot) use the RTS/CTS handshake associated with unicast transmissions. Consequently, GRAd exhibits very low latencies.

GRAd collects cost information opportunistically: each message carries with it the cost since origination, which is recorded at each node that overhears the transmission, and is incremented when the message is relayed. Thus, the simple act of passing a message quickly and efficiently updates the cost estimates in nearby nodes.

GRAd demonstrates very good immunity to rapidly changing topologies. Since each message reaches a number of neighboring nodes, a single link failure will not cause a break in the communication path as long as another neighbor is available to relay the message.

The GRAd algorithm

ASSUMPTIONS

GRAd is designed for use in multi-hop wireless networks, and makes relatively few assumptions about the underlying physical medium. It does assume that links are *symmetrical*: if Node A can receive messages from Node B, then Node B can receive messages from Node A. In a practical wireless network, strict symmetry is impossible to guarantee due to the mobility of the nodes and time-varying environmental noise. As will be shown in by simulation, GRAd continues to work well in cases where only partial symmetry holds.

GRAd assumes a local broadcast model of connectivity. When a node transmits a message, all neighboring nodes within range simultaneously receive the message.

GRAd provides best effort delivery of messages with the understanding that higherlevel protocols will handle retransmission and reordering of packets as needed. The propagation of a message through the network establishes and updates *reverse path* routing information to the originator of the message. Consequently, GRAd is most efficient when the network traffic has a "call and response" pattern, such as streamed packet data with periodic acknowledgments.

GRAD MESSAGE FORMAT

Messages passed among nodes in a GRAd network carry a header containing the fields shown in Table 2. A description of each field follows.

msg_t	ype o	originator_id	seq_#	target_id	accrued_cost	remaining_value
-------	-------	---------------	-------	-----------	--------------	-----------------

TABLE 2. GRAd message format

 msg_type : Takes on one of two values, $M_REQUEST$ for a reply request message and M DATA for all others.

originator_id: The id of the node originating this message. This id may be statically assigned, or may be dynamically generated on a per-session basis.

seq_#: A sequence number associated with the originator id, and incremented
each time the originator issues a new message. The combination of
[originator_id, sequence_#] uniquely identifies a message, so a receiving
node can distinguish a new message from a copy of a message already received.

target id: The id of the ultimate target for this message.

accrued_cost: Upon origination, the accrued_cost of a message is set to 0.0. When the message is relayed, the relaying node increments this field by one. Thus, accrued_cost represents the estimated number of hops required to return a message to originator id.

remaining_value: Upon origination, this field is initialized to the estimated number of hops to target_id. Whenever the message is relayed, this field is dec-

remented by one. The remaining_value field represents the "time to live" of the message: if it ever reaches zero, the message is dropped.

COST TABLE

Each node maintains a *cost table*, analogous to the routing table of other algorithms¹. The cost table plays two important roles in GRAd. First, the cost table can answer the question "Is this message a copy of a previously received message?" This is determined by comparing the seq_# in the message from a particular originating node against the last seq_# recorded in the cost table for that originator. Second, it can answer the question "What is the estimated cost of sending a message to target node X?" This cost estimate is formed by recording the accrued cost fields for each originator id in received messages.

COST TABLE FORMAT

Each entry in the table holds state information about a remote node, as shown in Table 3.

target_id seq_#	est_cost	expiration
-----------------	----------	------------

TABLE 3. Cost table entry

target_id: The id of a remote node to which this cost entry refers.

seq_#: The highest sequence # received so far in a message from target_id.
When compared against the seq_# of a newly arrived message, this field discriminates between a new message and a copy of a previously received message.

est_cost: The most recent and best estimated cost (number of hops) for delivering a message to target_id.

^{1.} The term "cost table" is chosen over the more conventional "routing table" to emphasize that GRAd does not prescribe a specific route to a target node, but rather it maintains an estimated cost to the target.

expiration: When a cost entry is updated, this field is set to the current time plus cost_entry_timeout. If the current time ever exceeds expiration, the cost entry is purged from the table.

COST TABLE MAINTENANCE

When a message is received at a node, the originator_id of the message is compared against the target_id of each entry in the cost table.

If no matching entry is found, a new cost entry is created, for which target_id is copied from the message's originator_id, seq_# is copied from the seq_# field, and est_cost is copied from the accrued_cost field. The message is marked as "fresh."

If a target_id is found that matches the originator_id of the incoming message, and if seq_# in that entry is lower than the seq_# of the incoming message, the message is marked fresh and the cost entry fields are updated from the corresponding fields in the message.

Otherwise, the message is marked as "stale"—it is a copy of a message previously received. However, if the messages offers a lower cost estimate in its accrued_cost field than the recorded cost in the est_cost field, the lower cost is recorded. This has the effect that if a copy of a previously received message subsequently arrives by means of a shorter path, the shorter path is recorded.

MESSAGE ORIGINATION AND RELAYING

When a node wishes to send a message to a destination for which the cost to the target is known, it transmits a message with the msg_type field set to M_DATA, specifying the destination in the target_id field and the cost to that destination in the remaining value field.

Of the neighboring nodes that receive the message, only those that can relay the message at a lower cost, as indicated by their cost tables, will do so. Before a neigh-

boring node relays a message, it debits the remaining_value field by one. As this process repeats, the message "rolls downhill," following an ever decreasing gradient from the originator to the target.

At the same time, the message carries the originator of the message in the origination_id field and the accumulated relay cost since origination in the accrued_cost field. Upon origination, the accrued_cost is set to 0. Each node that receives the message increments the accrued_cost field of the message and then updates its cost table entry for the originating node based on this information. If and when the message is relayed, it is re-sent using the incremented accrued_cost. By this process, any node that receives a message can update its cost estimate for returning a message to the originating node, whether or not the node is actively involved in relaying the message.

REPLY REQUEST MESSAGES

When a node wishes to send a message to another node for which there is no entry in the cost table, it initiates a "reply request" process. To do so, the originating node transmits a message whose msg_type field is set to M_REQUEST, specifying the destination in the target_id field and initializing the remaining_value field to default_request_cost.

Relaying of the message proceeds much in the same manner as for a M_DATA message, but with one important exception: any node that receives an M_REQUEST message will *always* relay the message the first copy of the message it receives, unless the remaining_value field has reached zero. As with an M_DATA message, the node will increment the accrued_cost and decrement the remaining_value fields of the message before relaying the message.

If a node receives a copy of a previously received message, it will update its cost table entry for the originator of the message if the copy represents a lower cost to the originator, but the node will not relay the copy.

Two important things happen in the reply request process. First, if the destination node is present anywhere in the network (within a radius of default_request_cost hops), it will receive the M_REQUEST message and initiate a reply. Second, each node that receives the M_REQUEST message establishes a cost estimate for returning a message to the originator. Consequently, when the destination node responds to the originating node's request, it can use the more efficient M_DATA message to deliver the reply.

CALL AND RESPONSE

GRAd is uses *on demand* routing: none of the nodes have any *a priori* knowledge of one another. Until a node turns on its transmitter, its presence in the network is not known to other nodes. The general rule for such networks is "if you wish to be spoken to, you must first speak."

The following two figures illustrate the Reply Request process in an ad hoc network, in which Node A initiates a request to Node B, and Node B subsequently responds. It is assumed that initially none of the nodes in the network have any knowledge about nodes A or B.

Figure 6 shows the state of the network after the propagation of a Reply Request message from Node A to Node B. The dashed circle around Node A shows the range of an individual transmitter. Node A starts by transmitting a Reply Request message with an accrued cost of 0 and a target_id set to the ID of Node B. The two neighbors to A each increment the accrued_cost field of the message, record the fact that they are each one hop away from A, and relay the message. This process

continues until all the nodes in the network have received and relayed the Reply Request message.

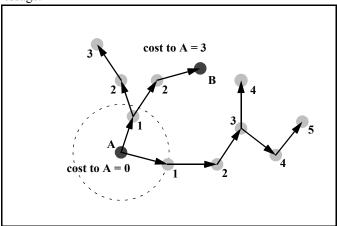

FIGURE 6. Reply Request from node A to node B

By the time A's Reply Request message has arrived at node B, all of the intervening nodes in the network have established a cost estimate for returning a message to A, as shown by the numbers next to each node in Fig. 1.

When Node B receives the Reply Request message from Node A, it responds by originating an "ordinary" message with msg_type set to M_DATA, accrued_cost set to 0, and remaining_cost set to 3, the known cost required to reply to Node A.

Referring to Figure 7, when B transmits this message, the neighboring nodes C and D lie within range and receive the transmission. The cost table of C indicates that A is two hops away, and since the message has an advertised remaining_cost of three, node C should relay the message after decrementing its remaining_cost. Node D, on the other hand, is four hops away from node A, and since it is unable to relay the message at a cost lower than the remaining_cost advertised by the message, it drops the message.

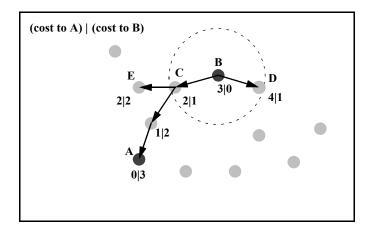

FIGURE 7. Node B replies using the reverse path

As the message is relayed towards A, intermediate nodes also create entries for returning a message to node B. Figure 7 shows the state of the cost tables after the reply has been received at Node A. Next to each node that participated in the reply, the estimated cost for sending a message to node A is shown to the left of the vertical bar, the cost to node B is shown to the right.

In this example, nodes D and E received the message from B, but did not actively participate in relaying it. Nonetheless, by virtue of "overhearing" the message, these nodes have established an estimated cost for sending a message to Node B should the need ever arise.

ROUTE REPAIR

As nodes in the network enter or leave the network, or move relative to one another, the topology of the network can change dynamically, rendering the individual nodes' cost estimates inaccurate.

If the path between originator and target becomes shorter, GRAd will automatically compensate for the change by "skipping over" one or more intervening nodes, and

the revised cost estimates will be reflected in the participating nodes' cost tables after a single call and response pair of messages.

In the event that the path become longer, or intervening nodes change their positions, there is the possibility that the originator's cost estimate no longer has sufficient "potential" to reach the target destination.

GRAd uses end-to-end acknowledgments. If an acknowledgment is not received within a fixed amount of time, the originator can re-send the message, but this time using a higher estimated cost to the destination in the remaining_cost field of the message. This has the effect that more intermediate nodes will participate in relaying the message towards its destination. As before, by the time the message reaches its destination, all of the intermediate nodes will have fresh cost estimates for returning a message to the originator, so the destination node's acknowledgement will be able to follow an updated gradient back to the originator.

If the first attempt to re-send a message with an increased estimated cost fails to reach the destination, the originator can repeat the process, incrementing the initial estimated cost each time.

If, after several attempts, the message fails to reach the destination, the originator can issue a new Reply Request message to create fresh cost estimates from scratch.

IMPLICIT ACKNOWLEDGMENT

To reduce the number of redundant messages transmitted, GRAd uses a variant of passive acknowledgment called *implicit acknowledgment*. A message to be relayed is stored in a MAC-level buffer while it awaits transmission. If a node overhears a neighbor relay a copy of that same message, but at a lower remaining_cost, then the node can assume that the neighbor has succeeded in delivering the message closer to the destination than this node, therefore it can delete the message from the MAC queue and cancel its transmission.

When the ultimate target node receives a message, it re-transmits the message with a remaining_cost set to zero. This has the effect of notifying any neighbors still waiting to relay the message that the target has received the message and that they may abandon their efforts.

Simulation and results of GRAd

Performance of GRAd was simulated using *Jasper* [Poor 2001], an event driven network simulator. The main objectives of the simulation were to characterize the performance of GRAd as a function of transmitted packets and the amount of mobility among the nodes in the network.

SIMULATION ENVIRONMENT

Jasper provides detailed models for components of a multi-hop, mobile, wireless ad hoc network.

The radio modelled by Jasper emulates an FM or spread-spectrum radio, such as would be used in a wireless local area network, operating in an urban or dense office environment. In the absence of other transmissions, a transmitter/receiver pair has a nominal range of 250 meters. Transmit power falls off as the cube of the distance, and a receiver can acquire lock on a transmitter if the signal to interference ratio exceeds 10db. Once locked, a receiver can hold lock as long as the signal to interference ratio exceeds 6db. During reception of a packet, if the signal to interference ratio drops below 6db, the packet is marked as corrupted. The bit rate of the transmitter is 2Mb/sec.

GRAd's MAC layer uses a technique of carrier sense with exponential backoff: when a node wishes to transmit a packet, it first waits for a random interval between T_b and $2T_b$ seconds. At the end of that time, if the carrier sense detects that the local airwaves are in use, it doubles the value of T_b (up to an upper limit) and waits again. If the airwaves are free, it halves the value of T_b (down to a lower

limit) and transmits the packet. If the MAC transmit buffer becomes empty, T_b is reset to its minimum value.

Mobility and traffic models were chosen to emulate those described in [Brooch 1998]. Fifty nodes in a 1500m × 300m arena travel according to the *random way-point* algorithm: each node travels towards randomly chosen locations within the arena at random speeds (evenly distributed between 0 and 20m/sec.). After reaching its destination, the node pauses for a fixed amount of time before setting out for its next randomly chosen location. The *pause time* is varied from 0 seconds for continuous motion to 900 seconds in which case the nodes are stationary for the duration of the simulation.

Traffic is generated by *constant bit rate* (CBR) sources, randomly chosen among the 50 nodes. Each CBR source targets a randomly chosen destination among the remaining 49 nodes. A CBR source generates four 64 byte packets per second. The load on the network is controlled by the changing number of CBR sources. In the tests, 10, 20, 30 and 40 CBR sources were used to generate traffic.

Messages from the CBR source sit in a queue until a route is discovered. To prevent indefinite buffering, messages are dropped if they remain in the queue for over 30 seconds.

Entries in cost tables are set to time out if not updated within four seconds.

In the simulation, a target sends a 32 byte acknowledgment to the CBR source once every two seconds. This acknowledgement message has the dual effect of notifying the CBR source that messages are reaching the target, but more importantly, it refreshes the path from the CBR to the target.

Each test was run for 900 simulated seconds and the results were averaged over ten consecutive runs in order to account for different network topologies.

EVALUATION AND DISCUSSION

Three key performance metrics are evaluated: (i) *Packet Delivery Fraction*—the ratio of data packets successfully delivered to those originated; (ii) the *Average Latency*—the measure of the total end-to-end delay in delivering a packet to a destination; (iii) *Normalized Routing Load*—the ratio of the total number of packets transmitted by any node to the number of packets successfully delivered to the destination.

Figure 8 shows the Packet Delivery Fraction as a function of pause time and for different numbers of CBR sources. As can be seen from the graph, GRAd is insensitive to variable mobility—the percentage of good packets delivered remains essentially constant as the pause time changes.

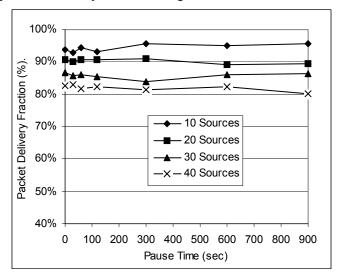

FIGURE 8. Packet delivery fraction

GRAd is robust in the face of changing topology because it enlists multiple neighboring nodes to relay messages from one place to another. If one node moves out of place, other nodes are often available to relay the packet without resorting to rebuilding the route.

Figure 9 shows the average end-to-end latency for successfully delivered packets. In GRAd, latency remains under 7 milliseconds, even under conditions of high mobility and load. By contrast, [Das 2000] reports end-to-end delays of more than 100 milliseconds, and as high as one second for heavily loaded networks. It must be pointed out that is not an exact comparison: in [Das 2000], packet size was 512 bytes and the radio is simulated using a different path loss model.

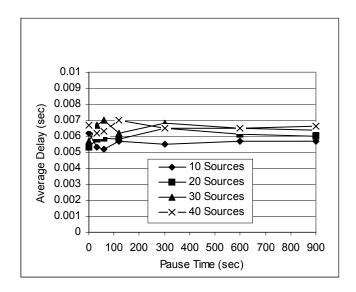

FIGURE 9. Average delay

In any practical implementation, GRAd is still likely to show small latencies since it avoids the RTS/CTS link to link handshake used in other protocols.

However, there is a price to pay for the "fast and loose" routing approach used by GRAd. Fig. 5 shows the routing load for various pause times and CBR sources.

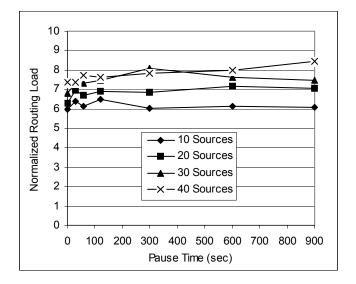

FIGURE 10. Routing load

As Figure 10 shows, for every one data packet received at the ultimate destination, between six and eight packets have been transmitted. Some of these "extra" packets are inevitable, for example, if a path requires two hops from source to destination, this will be recorded as a routing load of two. A destination node always sends an implicit acknowledgment notification, as described in the section on "Implicit Acknowledgment," which contributes to the load. Relatively few of the overhead packets are Reply Request messages, even in scenarios with high mobility². The majority of the overhead packets are due to multiple neighbors attempting to relay the same packet. A consequence of this overhead is that GRAd networks exhibit more congestion than other network algorithms for the same offered load.

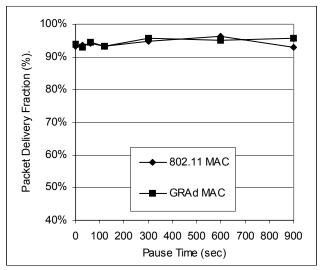

^{2.} In a typical test with 10 sources and 0 second pause time, only 2.5% of all messages transmitted were M REQUEST messages.

CHOICE OF MAC LAYER

In any ad hoc network, there is no centralized control to control access to the airwaves, so nodes depend upon the MAC mechanism to cooperatively share the airwaves. GRAd, in particular, taxes the MAC layer since multiple neighboring nodes will attempt to relay a message soon after receiving it. It was therefore suspected that performance of GRAd would be sensitive to the choice of MAC layer.

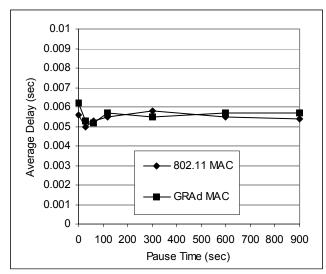

The 802.11 MAC layer [IEEE 1999] is considerably more "fair" than GRAd's simple carrier sense and exponential back off approach described in the section on "Simulation Environment." In the 802.11 approach, the MAC layer implements a countdown timer which is initialized to a random duration proportional to an exponential back off constant. The timer counts down only when the local airwaves are clear. When the timer expires, the MAC layer transmits the packet. This approach distributes air time evenly among neighboring nodes.

The tests were run for 10 CBR sources using the 802.11 MAC layer and compared against the same tests using the GRAd MAC layer—the results are shown in Figure 11. It is interesting to note that there was little effect on the overall performance of GRAd using two substantially different MAC layers.

DISABLING ROUTE REPAIR

A previous section describes GRAd's mechanism for Route Repair: if the receiver fails to receive a packet from a sender within the expected period of time, it sends a reply to the sender with an increased remaining cost.

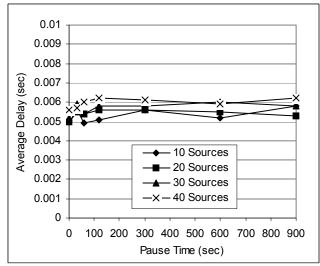

To gain insights to the effectiveness of the route repair mechanism, the tests were run with route repairs disabled: if the network topology changed so an originator no longer reached its destination (more accurately, if an originator stopped receiving packets from its destination), the entries in the cost table would time out and the originator would start a new Reply Request process.

Figure 12 shows the effects of disabling the Route Repair mechanism. The packet delivery fraction drops almost insignificantly, but somewhat surprisingly, the average latency and routing load are both improved.

Proposed extensions to GRAd

The results of GRAd are encouraging, but there are a number unanswered questions whose answers may give insights to the operation of GRAd and suggest areas for improvement.

CONSIDERING MORE THAN NUMBER OF HOPS

Throughout this chapter, the term "cost" has been used to mean "number of hops," but metrics other than the number of hops are possible. For example, a node can charge a higher cost for relaying a message if it notices that its local airwaves are becoming congested, or if its local topology is changing rapidly. The higher relay cost will cause messages to flow around the node if there are other nodes that can relay at a lower cost.

To generalize, in a multi-hop wireless network, the only real choice a node can make is whether or not to relay a message that it has received, and if so, when to relay it. As suggested in [Kramer 1999], it may be useful to structure the problem of routing as a set of software agents residing in the nodes and in the messages; the agents decide what should be relayed and when. The network can then be viewed as a series of *activation* and *inhibition* functions, the former causing a message to be transmitted, the latter preventing it [Intanagonwiwat 2000].

PREFERRED NEIGHBORS

GRAd and AODV share many traits, including on-demand route discovery and updating reverse path information as a message is relayed from one node to next. GRAd permits any neighbor to participate in relaying a message, AODV insists upon a particular neighbor. A compromise between these two approaches shows some promise: A relaying node advertises a cost for relaying a message (a la GRAd) and suggests a preferred neighbor to do the relaying (a la AODV). If that neighbor is not observed to relay the message within a certain amount of time, then non-preferred neighbors may attempt to relay the message. This approach could

reduce some of the routing overhead observed in GRAd while still maintaining robustness in dynamically changing networks.

FUNCTIONAL ADDRESSING

The broadcast nature of GRAd's Reply Request encourages *functional addressing*, in which a node initiates an M_REQUEST message containing a predicate rather than a specifying a fixed target ID. The predicate is a piece of software that embodies a query such as "Are you a color printer?," "Are you a gateway to a wired network?," or "Are you an ARP server?" Each receiving node evaluates the predicate and sends a reply to the requestor if the predicate evaluates to be true. If the requestor receives multiple replies, it can choose the reply that offers the lowest accrued_cost (i.e. is topologically closest) or that best satisfies some other application specific criteria.

PER-SESSION ADDRESSING

In GRAd, routes are created on demand, entries in cost tables are short lived and persist only for the duration of a dialog between two nodes. The identities of the intermediate nodes are not required for passing messages. This opens the possibility of *per-session addressing*, in which an originating and replying nodes choose network IDs at random to be used for the duration of a session.

The space of IDs can be made large enough so the chance of two nodes choosing the same ID is insignificant.

Per-session addressing offers two advantages. The first is security: by changing its advertised address for each session, a node gains some measure of anonymity and protection against malicious eavesdroppers.

Second, manufacturing costs are reduced since network IDs don't need to be assigned and individually burned in at the time of manufacturing.

Summary

GRAd offers a new approach to ad hoc, on-demand routing. Rather than sending unicast packets, it exploits local broadcasting to contact multiple neighboring nodes. Messages descend a cost gradient from originator to destination without needing to identify individual intermediate nodes. Cost functions are updated opportunistically as messages are passed from one node to the next.

Through simulation, the performance of GRAd has been tested and characterized under a variety of load and mobility conditions. The results of the tests show that GRAd exhibits very low end-to-end packet delays and offers good immunity to rapidly changing topologies.

CHAPTER 5 Distributed Synchronization

In a decentralized multi-hop network, it is often desirable to distribute shared information among all the nodes in the network. Since each node can communicate with only a subset of the rest of the network, information must propagate in multiple hops if it is to reach all of the nodes in the network.

Of particular interest are the dynamics of attaining synchronization across a network of nodes. Using today's technology, it is unreasonable to assume that nodes will be fabricated with permanent real-time clocks or will have access to a common wireless time base, such as Global Positioning System (GPS) timing information. Consequently, timing must be agreed upon dynamically.

The algorithm for distributed synchronization is simple: once every T_s seconds¹, node n broadcasts its internal time value, Ψ_n , to its neighbors. Upon receiving a message from a neighbor, a node adjusts its internal time to the average of its previous time and the time advertised in the message.

Given a network of N co-located nodes in which every node can receive the transmissions of all other nodes, it is easy to show that the maximum spread of the shared time will decrease by a factor of two each time a node broadcasts its value, or a factor of 2^N every T_s seconds.

Predicting the rate of convergence for networks that are not co-located is not so simple. The maximum error among the nodes depends on both initial conditions

In practice, the T_s interval will be randomized slightly to reduce the chance of repeated collisions among neighboring nodes.

and the order in which the nodes advertise their times, so a strict analytical approach is difficult. But using statistical models, it is straightforward to determine an upper bound for the rate of convergence.

In modeling the rate of convergence, the single most important parameter is the "diameter" of the network, where the diameter is defined to be the number of hops in the shortest path between the furthest pair of nodes. The worst case for convergence is when the nodes are arranged in a linear array with the node at one end of the array initialized to a maximum value (assumed in these tests to be 1.0) and all other nodes set to 0.0:

$$\Psi_n = \begin{cases} 1, n = 0 \\ 0, n \neq 0 \end{cases}$$
 (EQ 7)

A linear network of diameter 6 is shown in Figure 13, below.

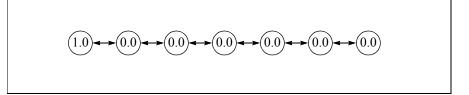

FIGURE 13. Linear network, diameter=6

Running the algorithm

At the beginning of each trial run, a random permutation P(n) on the set of integers 0...N-1 is generated. This determines the order in which nodes broadcast.

In the course of a single iteration, each node broadcasts its internal time value, Ψ_n , to its neighboring nodes, so that the function:

$$\Psi'_{n-1} = (\Psi_n + \Psi_{n-1})/2$$
 (EQ 8)
$$\Psi'_{n+1} = (\Psi_n + \Psi_{n+1})/2$$

is performed N times, once for each n.

In the results shown below, *deviation* is defined as the maximum magnitude difference from the mean of all Ψ_n , and *iterations* is how many iterations were required to bring the deviation below a given threshold.

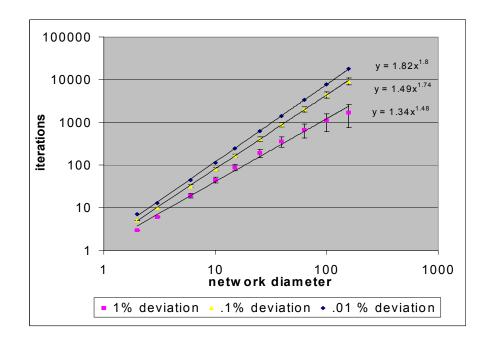

FIGURE 14. Time to converge increases exponentially with network diameter

Figure 14 shows that the number of iterations required to attain a given deviation increases exponentially with the diameter of the network. While theoretically troubling, this is unlikely to be a problem in practice. Both the constant and the exponent are small. To put this in context, a circular network of 1000 nodes and no overlap will have a diameter of 34. If every node in the network runs its algorithm once every second, the system is guaranteed to converge to within 0.01% of maximum deviation within approximately 1,000 seconds, or 17 minutes. For many applications, this is a trivially short amount of time.

Figure 15, below, shows deviation as a function of iterations for a variety of network diameters. It is reassuring to note that the deviation improves exponentially over linear time.

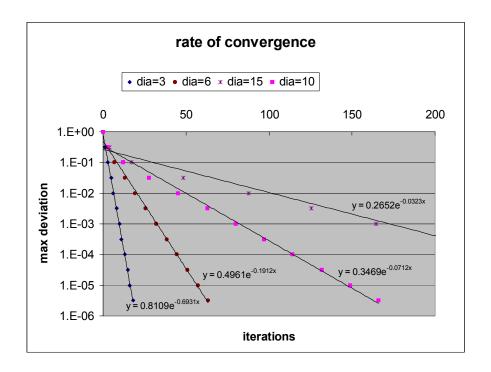

FIGURE 15. Convergence improves exponentially at each iteration

An example: synchronization for spread spectrum

Decentralized synchronization can be used to dynamically establish a common time base among nodes in a network. A common time base can be used to coordinate the hopping sequence in spread spectrum receivers in the network, dramatically reducing the time required to attain synchronization in the receivers. The 802.11 (FH) wireless Local Area Network standard specifies a hop duration of 10 mSec. If the receivers can tolerate a 10% timing error to attain synchronization, it is sufficient to synchronize the nodes within 1 mSec of one another. The hop sequence repeats

once every 660 mSec, so synchronization within 1 part in 660, or 0.15%, is sufficient.

If 100 nodes are arranged evenly in a circular area, the resulting network will have a diameter of approximately 11. By running the simulator (or by extrapolating from the Figure 15 above) it is shown that the system will converge in under 100 iterations. From a cold start, if each node transmits a timing beacon once every second, the system will attain synchronization in under two minutes.

Summary

These results show that a network can cooperatively establish a shared value where each node node periodically broadcasts its time information to its immediate neighbors and takes the average when receiving it. This approach is provably stable, and shows exponential reductions in maximum deviation in linear time for a given network diameter.

It is important to note that the figures given here are for worst-case initial conditions. Several factors can lead to substantial reductions in the time to attain a given deviation. First, perhaps contrary to intuition, mobility among nodes will tend to decrease the time required to attain a given deviation since mobility causes the errors to diffuse more rapidly.

The convergence time can be substantially reduced for nodes entering a pre-existing network simply by having the newcomers "listen but don't talk" for a period of time. This will cause the new nodes to converge rapidly on the values that the incumbent nodes have already agreed upon.

CHAPTER 6 Statistical Medium Access

Channel sharing

If it were necessary for a node to know the identities of its neighbors before communicating with them, how would the node discover their identities? In any network, it is often desirable to provide a communication channel to be shared among all nodes in the network. In a self-organizing network, this channel takes on special significance since it provides a mechanism for a node to share state information with its neighbors without any *a priori* knowledge of their individual identities.

Since this mechanism is used for network control and discovery, we will refer to this channel as the *control channel* through the rest of this section.

There are several ways to implement a shared channel in wireless systems, depending on the link layer communication scheme.

A DEDICATED LINK

A node can be built with two wireless links: one to carry network control information and the other to carry data packets. This approach has several advantages. The control channel link can be implemented as a low power, low bit rate radio. Its receiver can be always on, and the rest of the system lies dormant until a message is received. Additionally, this scheme does not require nodes to be synchronized to one another.

This approach has disadvantages. The cost of the additional radios may be significant. Due to differing propagation characteristics, connectivity among control channel links may be different from connectivity among the data channel links.

A DEDICATED TIME SLOT

Nodes can agree on a common time slot to be used for control information. The primary advantage of this approach is cost and simplicity: no extra radio systems are required.

There is a price to pay for this approach: all nodes must be synchronized to one another. This synchronization requires that nodes are aware of one another, which is at odds with the stated design goal that the control channel is the mechanism used for nodes to discover one another.

A DEDICATED SPREADING CODE

For systems that use spread spectrum communication, a predetermined spreading code can be dedicated to the control channel. This has the advantage that control information can be transmitted at any time with minimal impact on data transmissions.

Using a dedicated spreading code for the control channel requires that the radio receiver in every node has two demodulators—one for the data channel and one for the control channel. This will increase the cost and power consumption of the system. If the radio systems are to attain fast synchronization at the start of each packet, the nodes themselves must be synchronized to one another.

Medium Access and Collision Avoidance

Whether the control channel is implemented as a dedicated radio frequency, time slot or spreading code, it is still a shared resource and subject to contention. If mul-

tiple nodes transmit on the control channel simultaneously, there may be collisions resulting in lost information.

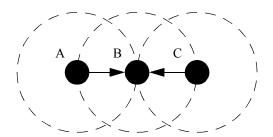

FIGURE 16. Collision

For example, the figure above depicts three nodes. Nodes A and C are within transmit range of node B. If both A and C transmit simultaneously on the control channel, B will not be able to discriminate between the two transmissions and the information will be corrupted, leading to lost data.

A statistical approach

In order for information to be conveyed on a shared channel in a given time slot, exactly one node must transmit. If zero nodes transmit data, no information is conveyed. Similarly, if two or more nodes transmit, there is a collision, and again no information is conveyed.

In statistical channel access, every node that wishes to communicate on a shared channel does so at an agreed upon time slot, but with some probability less than one. The goal is to find the probability that optimizes the chance of successful communication, in particular, that exactly one node transmits data.

Choosing p

If there is one receiving node within range of N potential transmitting nodes, and each transmitting node transmits with probability p, the likelihood of one and only one of the N nodes transmitting is given by:

$$f(p) = p(1-p)^{N-1}$$
 (EQ 9)

When p is set to zero, the transmitters never transmit, so f(0) is zero. When p is set to one, the transmitters always transmit, so if there is more than one neighbor, transmissions always collide. Somewhere in between the two, f(p) rises to a maximum, depending on the number of transmitters in the vicinity of the receiver. The plot below shows the "goodput," or probability of a successful transmission for different number of transmitters as p varies from 0 to 1.

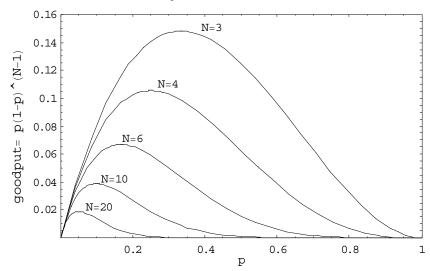

FIGURE 17. Probability of successful transmission

To find the value of p that maximizes the goodput, we take the derivative of (EQ 9) and solve for f'(p) = 0:

$$f'(p) = (1 - Np)(1 - p)^{N-2} = 0$$
 (EQ 10)

By inspection, it is easy to see that there are N-2 zeros when p=1 and one remaining zero when (1-Np)=0, or p=1/N.

This indicates that in order to maximize the goodput, a node that wishes to transmit to a particular receiver should do so with a probability of 1/N, where N is the number of transmitters wishing to transmit and within range of that receiver.

Likelihood of successful transmission

Substituting 1/N for p in equation (EQ 9) gives optimal goodput:

$$f(N) = \frac{(N-1)^{N-1}}{N^N}$$
 (EQ 11)

A plot of goodput versus number of nodes follows. The topmost line is the optimal goodput, attained when p is set to 1/N, where N is the number of transmitters that simultaneously wish to transmit. The two other curves correspond to p=.5(1/N) and p=2(1/N) to show the effect of non-optimal choice of p.

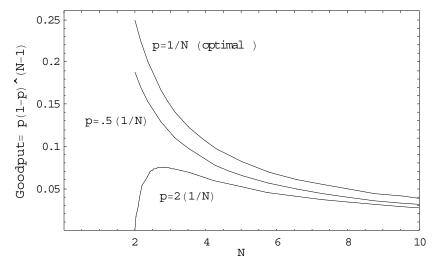

FIGURE 18. Adjusting p as a function of the number of transmitters

This is a function that falls off essentially as K/N, where N is the number of nodes that wish to transmit on the medium and K is 1/E, or 0.367879.

Statistical Medium Access in multi-hop networks

In multi-hop networks, it is often the case that multiple nodes attempt to relay an identical message on behalf of their neighbors. In this case, if N nodes are attempting to deliver the same message, it does not matter which one of the N nodes succeed. To reflect this, (EQ 11) can be multiplied by a factor of N, producing:

$$f(p)N = \frac{(N-1)^{N-1}}{N^{N-1}}, p = \frac{1}{N}$$
 (EQ 12)

As the following plot shows, the probability of successful transmission converges on 1/e (0.367879) as N increases.

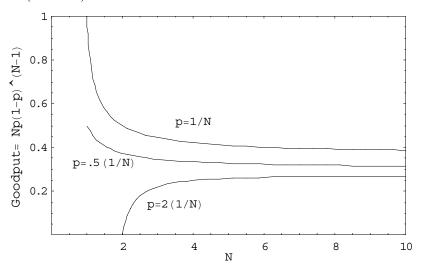

FIGURE 19. Goodput for any of N nodes succeeding

Misjudging N

In general, it is impossible to know exactly the number of neighbors surrounding the intended recipient of a message. What happens to the overall efficiency if sending nodes over- or under-estimate the node density?

To understand the effects of non-optimal choice of p, assume a constant node density—every node has N neighbors—and that every node wants to transmit.

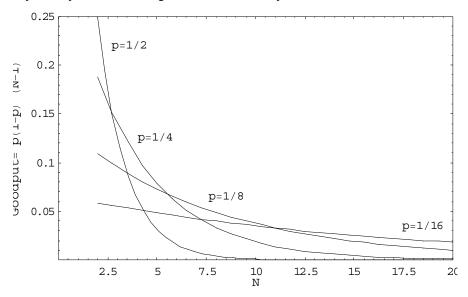

FIGURE 20. Overestimating and underestimating p

Figure 20 shows the likelihood of successful transmission using probabilities of 1/2, 1/4, 1/8, and 1/16. When p is chosen too large (as in underestimating N), the efficiency drops off quickly as the number of nodes increases. When p is chosen too small (as in overestimating N), the efficiency starts out lower than it would for optimal p and tapers off gradually.

Consequently, if the number of neighbors is not known precisely, it is better to overestimate N and choose a value of p smaller than optimal.

Summary

Statistical Media Access can provide a simple and fair mechanism for multiple transmitters to gain access to a shared communication channel in a decentralized network. In a multi-hop wireless network where each transmitter has limited range, Shared Media Access is ideal for broadcasting information to neighboring nodes. Unlike other media access strategies, such as MACA or MACAW, it is not necessary for each transmitting node to know the identities of the receiving nodes in order to initiate a transmission. All that is required for efficient communication is an estimate of how many nearby nodes wish to transmit. When multiple nodes are attempting to convey the same piece of information, worst-case efficiency is 1/E, or 0.367879.

CHAPTER 7 ArborNet: A Proof of Concept

Motivation

Up to this point, this dissertation has moved in the virtual domain, using statistics and simulation to predict the behavior of Embedded Networks. But there are insights to be gained by building physical systems and reducing theory to practice. Thus it was that ArborNet was created.

ArborNet is self-organizing network consisting of twenty-five wireless nodes. Each node is housed in a small weatherproof plastic box, and contains a microcontroller, a digital radio transceiver, three AA sized batteries, a collection of sensors, Light Emitting Diodes (LEDs) and assorted "glue logic." An ArborNet node with its clear plastic cover removed is shown below in Figure 21.

FIGURE 21. One of twenty-five ArborNet nodes

Hardware system

The heart of an ArborNet node is the "Constellation" board, designed by Andy Wheeler with assistance by the author. The Constellation board integrates a versatile 8-bit microcontroller with a short-range radio transceiver, and has proven itself to be a sound platform for network development and testing.

A block diagram of the primary components of the Constellation board is shown below in Figure 22.

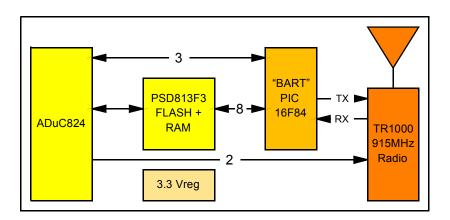

FIGURE 22. Constellation block diagram

PROCESSOR

The Constellation board is built around an Analog Devices ADuC824 microcontroller. The processor is a variant of the mature 8051 family of 8-bit microcontrollers, and contains a set of features that make it especially appealing for Embedded Processing applications.

Power: the ADuC824 is a low-power device for its class. The system uses a 32KHz watch crystal as its primary system clock which is frequency multiplied via a Phase Locked Loop (PLL) to 12MHz, giving a nominal instruction cycle time of 1 microsecond with excellent power management features. The processor draws a nominal

5mA while running, but can be put to sleep, during which time the power consumption drops to approximately 5uA.

Real Time Clock: The ADuC824 has an on-board Real Time Clock (RTC), which measures years, months, days, hours, minutes, seconds with resolution down to 1/128 of a second. When the main processor is put to sleep, the RTC keeps running, so time measurements are unaffected by processor sleep times.

Digital Input/Output: The ADuC824 has a large collection of input/output lines, with support for serial I/O, I2C and ISP devices.

Analog Telemetry: The ADuC has a high-resolution A/D converter with variable gain, multiplexed inputs—a design that made it easy to add sensors to the Constellation board with a minimum of additional circuitry. The ADuC824 also has a pair of 12 bit D/A converters, though they were not used in ArborNet application.

FLASH/RAM EXPANSION

Since the ADuC (and most 8051 based systems) are limited in RAM size, the Constellation includes a PSD813F memory and I/O expansion chip, manufactured by Wafer Scale Integration. The PSD813F adds 128KBytes of FLASH program memory and 2K of general purpose RAM to the system. It includes a JTAG programming port, which greatly speeds up development time during multiple revisions of the firmware.

The PSD813F also provides 32 general I/O ports. Some of these are dedicated to communication with the ADuC824, the remaining lines connect to LEDs and the BART radio interface (q.v.).

RADIO SYSTEM

The Constellation board uses the TR1000 radio transceiver, a single-chip device designed by RF Monolithics. It supports bi-directional digital communications at rates up to 115K Bits/second using an unlicensed ISM frequency band of 915MHz.

The antenna is an integrated patch device made by Lynx technologies. The radio system has been measured to communicate reliably at a range of 30 meters in an open space.

"BART" RADIO INTERFACE

The ArborNet radio communicates at a basic channel rate of 113,630 bits per second, requiring accurate 8.8 uSec timing per bit. To reduce the real-time processing requirements on the system microcontroller, the BART (Block Asynchronous Receive/Transmit) interface serves as an intermediary between the ADuC824 microcontroller and the radio. BART is implemented by a PIC16F84 microcontroller clocked at 20MHz.

To the microcontroller, the BART presents an 8-bit parallel port¹ with a 32 byte internal buffer. For the radio, the BART manages the serial data streams, providing accurate timing on transmit and byte- and bit-level framing on receive².

The BART provides DC balancing of the data: every 8 bits of host data is converted to 12 bits of DC balanced data upon transmission, and converted back to 8 bits upon receipt. The BART also generates and strips synchronization headers at the start of each packet, and doesn't initiate a transfer to the host microcontroller until a valid header is seen. This drastically reduces the amount of time the host microcontroller spends servicing spurious packets.

All higher level processing, including the generation and verification of per-packet CRC codes, is handled by the host microcontroller.

^{1.} The BART's parallel port actually connects to the PSD expansion chip, not to the micro-controller. From a programmer's point of view, the distinction is unimportant.

It is worth noting that the BART chip attains bit level synchronization of the received radio bit stream to within four processor cycles, or 800 nanoseconds, without the addition of special purpose hardware.

POWER SUPPLY

The ArborNet node is powered by three primary AA cells wired in series, which will deliver 4.5 volts when the batteries are new, drooping to under 2.4 volts over time. Since components on the Constellation board require a regulated 3.3 volts, a switching step-up/step-down voltage regulator has been included to provide a constant supply of 3.3V over the life of the batteries.

SENSORS

The Constellation board provides inputs for one high resolution (24 bit) and one medium resolution (16 bit) analog signals. In addition, the ADuC824 has an on-chip temperature sensor, calibrated in degrees Celsius. The Constellation board also connects a battery voltage monitor to one of the analog inputs on the ADuC A/D converter, so each node can monitor and report its own battery status.

Although the Constellation boards have been tested using photo sensors and external temperature sensors, the experiments described here use only the on-chip temperature and battery voltage sensors.

CONNECTORS

The Constellation board has number of connectors for communication and configuration, listed here.

Serial I/O	4 pins for serial input and output. Provides RX, TX, GND, +3.3V				
JTAG Port	14 pins. Used to program the microcontroller and PSD expansion chips.				
PIC programmer	6 pins. Used to program the on-board PIC (BART chip).				
Analog In	6 pins. Provides GND, +3.3V and two analog inputs.				
Jumper block	8 pins. Controls programming of the ADuC824 (_PSEN and _EA), and connects to two general purpose inputs on the ADuC824 for user configuration bits.				
I2C/SPI	6 pins. I2C and SPI high-speed serial interface for small peripheral devices, such as real time clocks, D/A converters, flash RAM.				

TABLE 4. Constellation's I/O Connectors

Software system

One of the design challenges for ArborNet was fitting the software system into an eight-bit microcontroller with limited code and data storage. For the task, a small real-time kernel, "RTX51 Tiny" by Keil Software, was chosen as the basic framework for the ArborNet system.

The bulk of the ArborNet system was implemented in 3300 lines of C code over a period of four months. The development tools from Keil were easy to use. The ArborNet system made extensive use of the RTX51 thread mechanism, which resulted in code that was easy to maintain and understand. Even though the RTX51 kernel offers round robin scheduling, it was disabled in the ArborNet system to simplify the coding and eliminate the risk of race conditions. Given this conservative approach, the RTX51 kernel proved to be robust: no system errors were observed that could be ascribed to the kernel.

The ArborNet packet mechanism

SERVICES, NOT LAYERS

Classic network architectures such as the Open Systems Interconnection (OSI) networking suite defines networking as a set of layers of abstraction, providing well-defined functionality and interfaces at each layer. A layer is designed as a "black box," hiding implementation details and communicating only its immediate superand sub-layers. This approach is designed to simplify the implementation and testing of network systems, but in hiding information at each level from other levels, information that is required at several layers must be replicated, leading to computational and storage inefficiencies.

Embedded Networking algorithms such as GRAd thrive on "hints," and can take advantage of all available information to increase the network efficiency. As an example, it can be useful for the MAC system in a wireless network to keep track of how many distinct neighbors are in the vicinity of the node—the MAC can use this

to predict congestion and adjust its holdoff times accordingly. In a typical layered network model, the MAC is precluded from examining any except the MAC header of received packets, so the network ID of the sending node must be included both in the MAC header as well as in the routing header.

This replication of information results in longer transmitted packets and more storage in the microcontroller. Since conserving power and storate are priorities in the design of Embedded Networking, ArborNet abandons the classic layered model in favor of a "services" oriented design.

LINKING, NOT ENCAPSULATION

In ArborNet, the basic unit of information transfer is a data *packet*—when the radio transmits data, it transmits a single packet. Each packet is implemented as a linked list of *segments*, where each segment carries a segment type and a payload specific to that type. The format of each segment is published and comes with a set of software functions to access the specific fields.

Consequently, any software module in the ArborNet system is allowed to examine an entire received packet for segments that it might find useful. On transmission, a packet is formed quickly and efficiently by pushing segments onto a linked list and is passed around as a single unit—no copying of memory is required as it would be for an model that uses encapsulation.

Software modules may "decorate" a packet, augmenting the information carried by the packet simply by pushing additional segments onto it. As an example, this technique was used to add networking statistics information to packets to ArborNet during system testing and debugging.

PACKET MEMORY MANAGEMENT

The Constellation board has only 2KBytes of RAM memory, which is dominated by packet buffer storage. In this limited environment, the use of linked segments for representing packets made memory management unexpectedly efficient.

The message packet system is initialized with a pool of fixed-size segment structures, all linked into a single freelist. When any software module wishes to allocate a segment, the next available segment is simply removed from the head of the freelist. Each segment is filled in with its segment type, segment size and any appropriate data. When a software module is finished with the segment, it is pushed back onto the freelist.

The size of the fixed-length segment structure is chosen to be long enough to hold the longest segment data. Consequently, many segment types don't fill out the entire segment storage. During radio transmission, the segment is compressed by sending a single byte length field followed by the segment type and only as many bytes of the segment payload as are actually used. Upon reception, the inverse process takes place: compressed segment structures are expanded out into fixed length segments as they are received, the component segments of a packet are linked into a single list and, if the packet is observed to be free of errors, passed to other software modules for processing. After the last software module has processed the packet, the entire packet is returned to the segment freelist.

PACKET SEGMENT TYPES

The ArborNet system implements the following segment types.

SEG_GRAD	Gradient Routing segment. Contains originating node ID, destination node ID, packet sequence number, accrued cost and remaining budget.
SEG_DISCO	Gradient Discovery segment, identical in content to a SEG_GRAD packet, but obeys different rules for relaying.
SEG_COST_L SEG_COST_H	Cost Table segments, containing the contents of the originating node's cost tables. This is split into two segment types, one for the low half of the table and one for the high, because of hardware limitations on the maximum packet size.
SEG_STATS	Node Statistics segment used for debugging and network testing. Contains various statistics, such as the number of packets originated, number of packets received, number of packet relayed.
SEG_TELEM	Telemetry information. Contains the readings of the sensor array on the originating node.
SEG_ARQ	Automatic Retry Request segment. The packet carries with it the retry ID and a number of retries remaining before giving up.
SEG_ACK	Acknowledgement segment, sent in response to a SEG_ARQ. Contains the retry ID of the SEG_ARQ being acknowledged.
SEG_APPX	Request for Application Transmission segment. The packet names a destination node that is requesting regular updates in the form of SEG_COST_L, SEG_COST_H, SEG_TELEM, SEG_STATS and SEG_TIME packets from the receiving node.
SEG_PING	Ping segment. Contains node ID and local system time. Used to advertise presence and synchronization information to neighboring nodes.
SEG_TIME	Time and synchronization status. The packet contains the sending node's current time, the maximum timing error recently seen and the number of SEG_PING packets generated and received.

TABLE 5. Segment types in ArborNet

Data flow in ArborNet

The ArborNet system is implemented using a number of threads and packet queues.

Figure 23 below shows the arrangement: rounded boxes represent processing

thread, bracketed boxes represent packet queues, and lines with arrows trace the flow of packets.

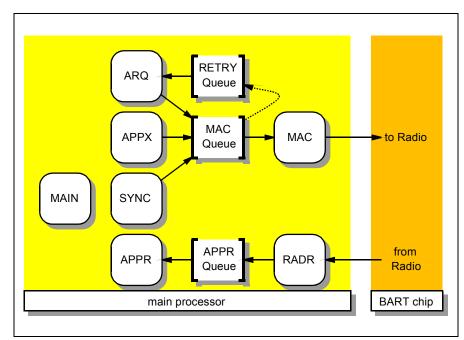

FIGURE 23. Threads and data paths in ArborNet

MAIN THREAD

The Main thread handles the initialization of the system, spawning all the other threads. Once the system is running, it monitors the RS232 serial input line for commands and displays the synchronization status of the real time clock by flashing the on-board yellow LED once every two seconds.

ARQ THREAD

The ARQ thread manages the retransmission of ARQ (automatic reply request) packets. A full description of the ARQ mechanism is described below in "ARQ processing."

SYNC THREAD

The Sync thread generates periodic "ping" packets that broadcast the nodes's Real Time Clock timing information to its immediate neighbors. Upon receiving a ping packet, the system adjusts its Real Time Clock as described in Chapter 5, "Distributed Synchronization." Implementation details of the synchronization mechanism are described below in "Timing services."

APPR THREAD

The Application Receive thread monitors the APPR queue, waiting for packets received by the radio mechanism to come available. When a packet is inserted in the APPR queue, the APPR thread wakes up, removes the packet from the queue, and distributes the packet on a segment-by-segment basis to other software modules. For example, if the incoming packet contains a segment of SEG_TYPE_PING, it passes the packet to the synchronization system for processing.

The APPR thread also prints the contents of each incoming packet in hexadecimal form to the serial output port. This is useful for debugging³, but is designed so any node can be a "gateway node" and log incoming packet data via the serial port.

APPX THREAD

The Application Transmit thread is responsible for sending periodic status reports to a remote node. It waits until it receives a packet containing SEG_TYPE_APPX, that identifies a node wishing to receive status reports and how often those status reports should be sent. It then enters a loop, composing and transmitting cost table

^{3.} The printing of each received packet almost certainly results in some dropped packets:

Due to the non-preemptive scheduling of threads, if a new packet arrives while the system is printing another packet, the 32-byte BART FIFO can overflow, resulting in a truncated packet which will be discarded due to a CRC mismatch.

reports, analog sensor readings, synchronization status, and packet statistic packets to the requesting node.

As written, the APPX thread sends a packet on the average of once every ten seconds.

MAC THREAD

The Medium Access thread monitors the MAC queue for available packets to transmit. When a packet becomes available, the MAC thread delays for a random hold-off interval, using the 802.11-style exponential backoff technique described in the chapter on Gradient Routing. When the holdoff expires, the radio transmitter is set to transmit mode and the packet is passed to the BART radio interface for transmission.

RRCV THREAD

The Radio Receive Thread waits for an interrupt from the BART radio interface, announcing the arrival of a new packet, and proceeds to read bytes from the BART as they become available. Upon reading the end of the packet, the Radio Receive Thread verifies the packet. If the packet is valid, it is stored in the APPR queue and the APPR thread is notified of its arrival.

ARQ processing

ArborNet implements a simple but effective Automatic Repeat Request (ARQ) mechanism. As described in Chapter 5, Gradient Routing works by using reverse path routing information, so sending occasional acknowledgements to an originating node is a natural and useful mechanism for keeping the routing information up to date⁴.

Prior to transmission, an application may augment any packet that contains a GRAd routing segment with an ARQ segment (of type SEG_TYPE_ARQ), containing an

ARQ reference number and a retry count. The packet is subsequently inserted in the MAC queue for normal transmission.

When the MAC module removes a packet from its queue just prior to transmission, the packet is examined. If the packet contains an ARQ segment and the retry count of the segment is non-zero, a copy of the entire packet is installed in the ARQ's Retry Queue. The original packet is transmitted as normal.

Whenever a packet containing an Acknowledgement segment (of SEG_TYPE_ACK) is received, its reference number is compared against that of each ARQ segment of packets waiting in the Retry queue. If the reference number matches, the corresponding packet in the Retry queue is removed and freed—it has been acknowledged and no further retries are required.

Concurrently, the ARQ thread is run whenever a packet is installed in the Retry queue. It sets a time-out counter before attempting retransmission (typically 500 milliseconds). After the time-out expires, the ARQ thread checks to see if there is still a packet available in the Retry queue, since the queued packet may have been acknowledged and removed in the interim. If the packet is still available at the end of the timeout period, its retry count is decremented and its routing header updated before installing it in the MAC queue for subsequent transmission.

When a node receives a packet containing an ARQ segment, it responds by creating a packet with an Acknowledgement segment (of type SEG_TYPE_ACK) with a matching reference number and sending it to the originating node.

^{4.} In the experiments described later in this chapter, the ARQ retry count was set to zero. This means that the recipient would generate ACK replies, but an unreceived ACK never results in retransmission of the original message.

Timing services

ArborNet nodes implement the synchronization mechanism previously described in Chapter 5, "Distributed Synchronization." This section describes the details of the implementation.

In an ArborNet node, local time is represented by an integer indicating 1/128ths of a second and is taken modulus 7680. Consequently, the system has a time resolution of 7.8125 milliseconds and cycles once every minute. These values were chosen based on the resolution of the ADuC824 Real Time Clock hardware and the limits of imposed by representing values in a sixteen bit unsigned integer. As an implementation detail, the current time is formed by reading the Real Time Clock and adding its value to an offset. When adjusting the local time, ArborNet code never explicitly sets the Real Time Clock, it only modifies the local offset.

A ping segment has the following fields:

fNodeID	Node ID of the transmitting node.
fTimeX	Local time of the sending node.
fTimeR	Local time of the receiving node.

TABLE 6. Contents of a SEG_TYPE_PING packet

The purpose of the SYNC thread is to broadcast the node's local time to its immediate neighbors quasi-periodically. The thread first pauses for a randomly chosen amount of time between 0.5 and 1.5 seconds then generates a packet containing a single ping segment (of type SEG_TYPE_PING). Although the segment contains a structure slot for the local time (fTimeX), it isn't filled in yet. The packet is installed in the MAC queue for transmission like any other packet.

The MAC contains code for special handling of SEG_TYPE_PING segments. At the onset of *every* transmission, the MAC code caches the local time. While the packet is being copied into the transmit buffer for processing by BART, if a segment of type SEG_TYPE_PING is detected, the previously cached time is written into the

fTimeX slot of the segment. This technique eliminates any timing jitter introduced by the MAC exponential backoff mechanism.

Similarly, upon receipt, the Radio Receive mechanism caches the local time when a packet first starts to arrive. In the course of reading the packet, if the Radio Receive code detects a segment of type SEG_TYPE_PING, then it copies the cached local time into the fTimeR slot. The packet is then installed in the Application Receive queue like any other packet. This technique eliminates any timing error that would result while the packet sits waiting for processing in the Application Receive queue.

When the Application Receive thread eventually dequeues the packet, it is passed to the synchronization mechanism for processing. There, the error between fTimeX and fTimeR is computed and the system clock is advanced or retarded by one half of the error.

In addition to its role as keeper of local time, the synchronization system also maintains statistics on how many ping packets were sent, how many were received, and a measure of the maximum timing error observed recently. These statistics are made available for transmission in a SEG_TYPE_TIME segment whenever the application transmit thread requests them.

Field tests and results

ArborNet was subjected to field tests in two different locales. The first tests were conducted in a residential setting, for which the nodes were placed around the author's house and garden. Other tests were conducted in an office setting: the nodes were distributed around the fourth floor of the MIT Media Laboratory.

A summary of the tests are show in Table 7, below.

Test name	Locale	Start Time	End Time	Duration	# nodes
Residential I	Residence	01:16	08:04	7h50m	15
Residential II	Residence	08:15	12:15	4h00m	15
Office I	Media Lab	21:00	00:00	3h00m	21

TABLE 7. Field test overview

In each test, node A ("Aspen") was designated as the collection point and gateway for ArborNet data. Its serial port was connected to a laptop computer which was used to log the incoming data for subsequent analysis. Tests ranged from three hours to nearly eight hours, during which time over five megabytes of raw data were collected.

The logged data consists of reports from each node in the network as it was received wirelessly at the central collection point. Reports gave a historical view of the state of each node at ten-second intervals, describing the node's cost tables, synchronization status, packet reliability statistics, on-chip temperature and system battery voltage.

Topology tests

As part of the GRAd routing mechanism, each node maintains a cost table indicating the cost (or number of hops) required to relay a packet to a particular destination. This cost estimate is formed by observing how many hops were previously required to receive a packet from the destination node. Inherent in this technique is the assumption of symmetrical communication channels: if node X can receive packets from node Y, then it is assumed that node Y can receive packets from node X. In practice, radio links are not symmetrical.

Since each node reports its routing costs for all the other nodes, and since that data is collected at a single point, it is possible to derive full connectivity graphs for the network. Two such snapshots are shown below in Table 8 and Table 9. Each row

displays one node's costs, measured in hops, to the node in each column. An asterisk indicates an unknown cost. If the system has completely symmetrical links, the graph will be symmetrical around the diagonal.

A few things can be observed from these graphs. Nodes E, G, P, and U (aka Elder, Ginkgo, Pear, Sycamore, and Uri) were not active during these tests, and as the gateway, node A (Aspen) did not log reports on itself.

The smaller network deployed in the residential setting displays nearly perfect symmetry. Few of the paths require more than one hop and the physical environment didn't pose a challenge to RF communications: the paths were short and there were no significant sources of RF interference.

TABLE 8. Connectivity graph for Residential I and II tests

The cells of the table that correspond to asymmetrical links are highlighted in gray in these tables. For clarity, only cells on the lower diagonal of the table are highlighted.

The connectivity graph for the Office I test paints a different picture, as seen in Table 9 below.

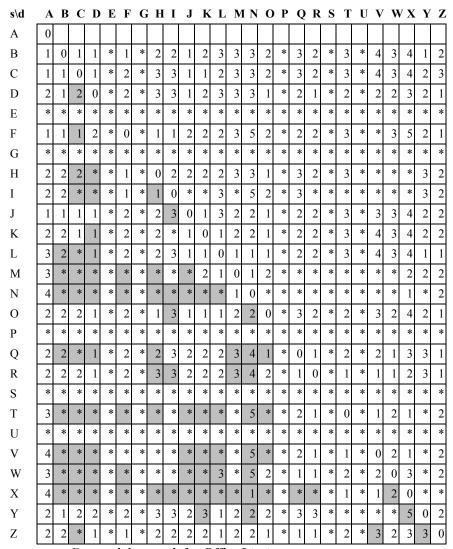

TABLE 9. Connectivity graph for Office I test

The network is not only larger, but the paths are longer and asymmetry is prevalent. The Media Lab is a modern office building with concrete load-bearing walls, metal doors and equipped with wireless networking gear competing in the same 915MHz frequency band as the ArborNet transceivers.

A diagram of the physical layout of the Media Laboratory and the placement of the nodes offers some additional insights to the network, shown below in Figure 24.

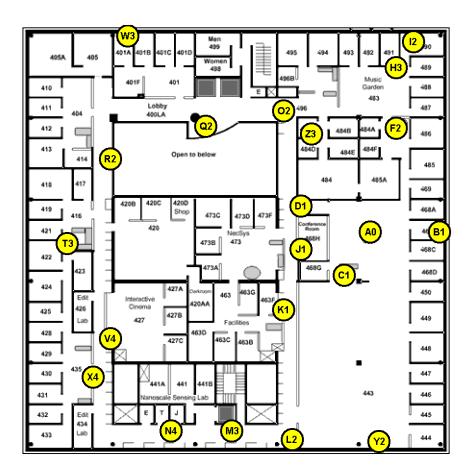

FIGURE 24. Layout of nodes in Office I test

Each circle represents the placement of a node. The letter is the node ID, the number is the number of hops from the central collection point (node A) located in Room 468 towards the east side of the building.

One thing to note is that physical distance is not necessarily a good indicator of the number of hops requires to relay a message. For example, node H (Holly) reported a cost of three hops to relay a message to node A, while node I (Ironwood) required only two hops, even though it was further away and on the far side of a metal door.

Received packet error rates

Each node keeps statistics on packets transmitted and received and reports these statistics back to the data collection node in SEG_TYPE_STATS packets. One set of statistics is maintained by the radio receive process, and simply logs how many packets are received with valid CRCs and how are invalid. A rough measure of the quality of reception at each node can be had by computing

$$\frac{validPackets}{validPackets + invalidPackets}$$
 (EQ 13)

This success rate for the Office I is shown for each node below in Figure 25. These figures do not account for packets with damaged synchronization headers since such packets are filtered out by the BART radio interface chip without notifying the host processor.

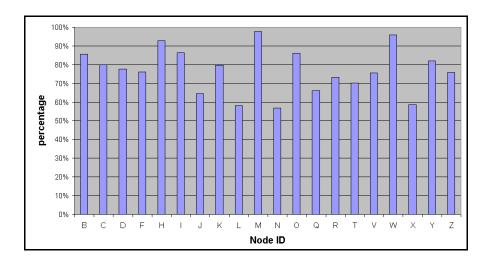

FIGURE 25. Percentage of packets received with valid CRC

It can be seen that nodes J, L, N, and X have marginal reception, as evidenced by their low percentage of valid packets received. Although not shown in the floorplan, nodes L, N and X are relatively isolated and separated from other nodes by steel fireproof doors, which could account for their poor reception. It is not clear why node J has poor reception. It is located near a 915MHz wireless network access point, but so are nodes D and K, which didn't suffer from poor reception.

Goodput tests

While the number of valid packets received is one way to characterize the network, it doesn't answer how successful the network is in relaying messages back to a central collection point. A more significant measure is the ratio of the number of packets originated at each node versus the number of good packets received at the collection point, or the "goodput."

Nodes were programmed to transmit a status report to the central collection node approximately once every ten seconds, so in the course of a three hour test one would expect 1062 reports from each node. An examination of the log files show that three nodes stopped transmitting before the full three hours had elapsed, so in measuring the goodput, number of transmitted nodes was prorated by the duration of the each node's lifetime. Figure 26, below, shows the goodput for each node.

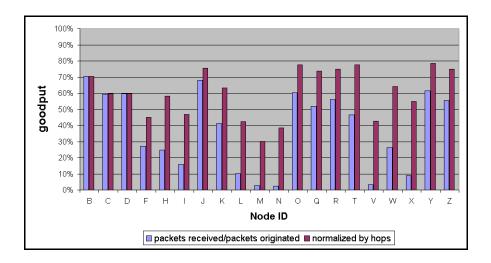

FIGURE 26. Goodput versus node

For each node, two values are shown: one is the goodput, which is simply the ratio of the number of packets received to the number of packets originated. The other value is the goodput normalized by the number of hops:

$$norm = goodput^{1/(hops)}$$
 (EQ 14)

which is a measure of the average reliability of each link independent of the number of hops.

This goodput shows some unexplained anomalies compared to Figure 25. For instance, node J showed a high percentage of bad received packets (as seen in Figure 25), yet is among the most successful at delivering packets to the collection point (Figure 26). It is possible that there is something about the placement or even the fabrication of the node that makes its radio receiver less sensitive.

By contrast, Figure 25 showed that Node M was able to receive packets reliably, yet it shows the poorest performance in delivering packets to the collection point.

Looking at the floorplan in Figure 24 offers a hint as to what might be going on.

Packets from node M are relayed through node N, which is demonstrably bad at

receiving packets. It is likely that N is dropping many of the packets that M expects it to relay on its behalf.

Despite these low percentages, most of the network continued to deliver reliable data over the course of the test. Many of the techniques described in GRAd were omitted in these tests, including timing out of cost table entries and Route Repair, so higher goodput should be easily attainable.

Distributed temperature sensing

A network of simple temperature sensors can detect when a house mate is taking a shower or when a cloud passes overhead. Each ArborNet node is equipped with a temperature sensor incorporated into the ADuC microprocessor. The microprocessor itself consumes about 15 mW of power, so it contributes little to the overall heat of the system. When located away from direct sunlight, the air temperature inside the box is a reasonable approximation of the external air temperature, making it a useful tool for measuring the ambient temperature.

For both residential tests, ArborNet nodes were scattered indoors as well as out-doors, so a single data collection point served to measure the entire environment. A plot of the indoor temperatures, measured between 8:15 AM and 12:15 PM on a chilly Cambridge day tells an interesting story, as shown here in Figure 27.

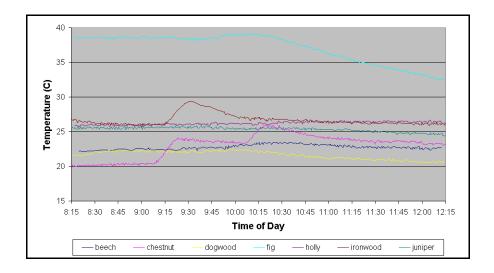

FIGURE 27. Residential II: indoor temperatures

The plot of indoor temperatures shows several significant features. The downstairs rooms (as measured by Beech, Chestnut and Dogwood), are approximately four degrees colder than the upstairs rooms (measured by Holly, Ironwood and Juniper). Ironwood, located in the upstairs bathroom, detected someone taking a shower at 09:15. The water and drain pipes run alongside the downstairs bathroom, causing it to warm up as well (Chestnut). Fig reports that the utility closet, containing the furnace for the baseboard heaters, is a balmy 37 degrees during the night as it struggles to keep the house warm, but cools off by more than ten degrees during the day as the rising outdoor temperatures reduce the thermal burden on the furnace.

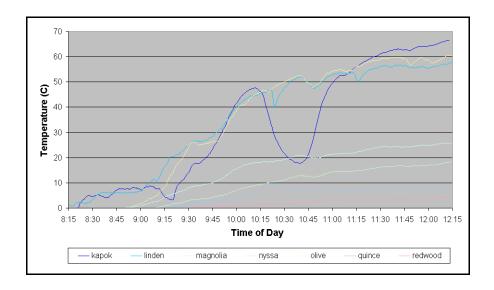

FIGURE 28. Residential II: outdoor temperatures

A plot of the outdoor temperatures, measured by the same network over the same period of time, shows even greater dynamics. The night air was below freezing, but temperatures climbed after sunrise. The temperatures in ArborNet node packages subjected to direct sunlight (Kapok, Linden, Magnolia) rose quickly to above 60 degrees. Kapok was located below a horizontal plank that acted as a gnomon, casting a shadow on it between 10:15 and 11:00 and causing it to cool. A cloud passed overhead around 10:50, as evidenced by a dip in temperature across all of the outdoor nodes.

It is significant that nodes equipped with something as simple as a single temperature sensor can be linked in a distributed network to glean information that would not be possible from more complicated sensors located at a single source.

A temperature graph created from the Office I test shows considerably less movement over time than the residential tests, as shown in Figure 29 below.

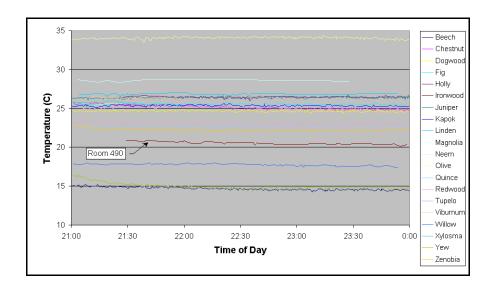

FIGURE 29. Office I: building temperatures

Three of the nodes (Beech, Willow, Yew) are located on metal window sills, so they register a temperature much colder than the rest of the building. Nodes Magnolia and Olive were placed on top of lighted exit signs, thus registering a considerably warmer reading. But one office, Room 490 as reported by Ironwood, clearly stands out as several degrees colder than the rest of the building.

When dense networks of sensors are located in and around office buildings, maintenance personnel can monitor large heating and air conditioning systems continuously and to a level of detail not otherwise possible, which will lead to less wasted energy and happier building occupants.

Battery power: trends and outliers

As previously stated, it is important for nodes in a self-organizing network to be as autonomous as possible. In a typical network, nodes that are powered by batteries can be problematic, since it may not be clear if a loss of communication is due to the batteries running out or due to some other failure.

Nodes in ArborNet include an on-board battery monitor (measured before the voltage regulator), and are programmed to report their battery status regularly to the central data collection point. The table below shows the battery voltages in each node at the start and end of each of the three field tests, as reported wirelessly to the logging node.

	Resident	ial 1	Resident	ial II	Office I

TABLE 10. Battery voltages before and after each field test.

Even after a total of fifteen hours of service, the voltage in most of the batteries is still over 4.1 volts. It is clear that node B and F (Beech and Fig) were used for additional tests before the start of the field tests, and that the batteries in nodes T through Z (Tupelo through Zylosma) were fresh at the start of the Office I test.

Being able to continuously monitor the supply voltage of each node has already shown itself to be an important feature in the development and maintenance of battery powered wireless nodes. By reading many nodes at once, it is possible to detect overall trends as well as individual exceptions.

Synchronization

The nodes in ArborNet implement the synchronization techniques described in Chapter 5, "Distributed Synchronization." To verify correct operation of the synchronization algorithm, each node issues regular reports on its synchronization state, indicating the node's local time, the maximum short-term inter-node timing difference, and the number of SEG TYPE PING packets issued and received.

The real time clock on the Constellation board has a resolution of 1/128 of a second, which sets ArborNet's limits of synchronization⁵. The synchronization status reports will only report synchronization to within 3/128 of a second, even while the internal synchronization is more accurate⁶. Consequently, the minimum reported error will be never be less than 23.4 milliseconds.

A graph of the error distribution of the synchronization reports in the Office I test indicate that nodes are synchronized within 300 milliseconds of their neighbors over 93% of the time, shown here in Figure 30.

^{5.} This resolution could easily be improved by using software or hardware phase locked loops.

^{6.} The short-term timing difference decays exponentially as each PING packet is received. The exponential decay is computed using simple integer arithmetic and errors less than 3 are internally truncated to zero. Fixpoint arithmetic would solve the problem handily.

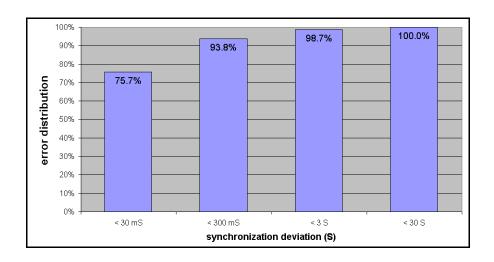

FIGURE 30. Distribution of Synchronization Deviation

However, that there are any errors greater than 300 milliseconds is unexpected. A snapshot of the individual synchronization errors across five nodes offers a some insights, shown below in Figure 31.

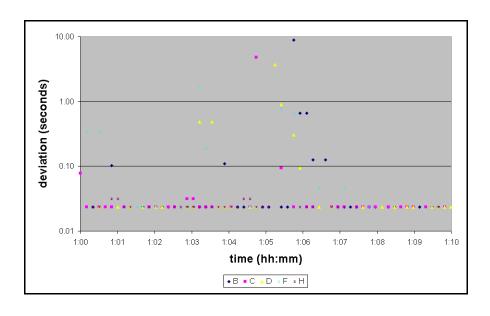

FIGURE 31. Individual synchronization deviation (10 minute snapshot)

Plotted on a logarithmic scale to accentuate the errors, it can be seen that the nodes report the minimum synchronization error (23.4 milliseconds) most of the time, but occasionally report errors in excess of one second. These errors do not appear to be the isolated to individual nodes; whatever the source, the errors spread like small firestorms through all the nodes in the network.

Although the log files don't capture enough information to pinpoint the source, it is possible to make some educated guesses as to the cause of the errors.

One unlikely scenario is that the real time clocks internal to the ADuC824 exhibit sufficient drift that they will fall out of synchronization after a few minutes. If a node is isolated from its neighbors for an extended period of time due to transmission errors, when it finally manages to exchange a SEG_TYPE_PING packet with its neighbors, its internal clock has drifted sufficiently far that it causes a ripple of synchronization error to be propagated through the network. However, the 32.768 KHz crystals used for the Constellation board's timing have an accuracy of 20 parts per million, or about 1.2 milliseconds maximum drift per minute, which doesn't explain the large timing deviations observed in the network.

A more likely cause of these errors is that nodes incorrectly exchange their internal time reference with their neighbors. For example, if the advertised synchronization information was constantly slightly behind the node's internal real time, then all the nodes in the network would retard their internal clocks as a group. However, if one node fell out of communication with other nodes, it would be free to run at the proper speed. When it re-establishes communication with other nodes, it would cause a large perturbation in the overall synchronization of the network.

A solution to this problem will require more detailed data collection and analysis. Despite these occasional timing errors, the fundamental goal has been achieved, showing that nodes can synchronize accurately to one another in a decentralized network.

CHAPTER 8 Conclusions & Future Work

Because it has no other means to communicate, a smoke detector in the basement can only scream when it detects smoke and beep futilely when its batteries run low. Given a more sensible means of expression, it could do a much better job of protecting a home and its occupants.

Microprocessor chips have already reached the point where their usefulness is not limited by their processing power, but rather by a lack of context. Isolated from the rest of the world, the majority of these chips can neither sense the world around them nor participate in any meaningful discourse with other chips in their environment.

Some lessons learned

This thesis has presented *Embedded Networking*, an integrated approach to scalable, self-organizing networks designed to give voice to microprocessors. Several good and surprising results have arisen in the course of developing this art.

Embedded Networks are attainable. Embedded Networks can be built today. A practical implementation does not hinge upon as-yet-undeveloped technologies or exotic components. Because Embedded Networking has been designed to be "radio agnostic," it can use existing radios and still take advantage of the inevitable developments in new wireless technologies.

Data aggregation is a powerful tool. It is astonishing how much can be learned by having multiple data points. As an example, the interplay of outdoor temperatures, measured at just seven different points during the course of a sunrise, told a much more interesting story than seven readings from one sensor possibly could.

Embedded Networks must be proactive. David Tennenhouse is right: if computing systems are to become useful, they must do so with a minimum of attention from their human stewards [Tennenhouse 2000]. For example, it proved to be remarkably useful to have each node in the ArborNet proof of concept system monitor its own battery voltage. This simple approach removed doubts as to whether nodes were running low on power or not. As an unexpected benefit, it proved very easy to answer the question "do alkaline batteries run down faster when they are subjected to sub-freezing temperatures?" (The answer was that they did not drain appreciably faster than their warmer neighbors.)

Gradient Routing works in theory and in practice. Gradient Routing, a cornerstone of the Embedded Networking systems described here, proved itself to be an effective technique. It succeeded in relaying data packets from one wireless node to another without either the need for preplanning the network or for human intervention during its operation.

Unturned Stones

Paradoxically, the hallmark of satisfying research is that it leaves one hungry to do more, and the work here has been no exception. This early exploration into the theory and practice Embedded Networking has perhaps raised one new question for every question answered. A few of these "unturned stones" are offered with the thought that they might prove to be interesting and worthwhile avenues for further research

DEEPEN UNDERSTANDING OF RADIO PROPAGATION

It would be informative to conduct a detailed study of the connectivity characteristics among all nodes in a network, directly measuring the bit error and packet error characteristics between each combination of nodes. Although the error rates will depend upon radio technology and environment, some other questions will fall out as a direct consequence: How symmetrical are wireless communication links in

practice? What is a good estimate of path loss, and how well does spatial division multiplexing work? How closely does physical topography correspond to network topology? This kind of information is typically difficult to gather, but a decentralized multi-hop wireless network such as ArborNet makes it quite easy.

BUILD A WIRELESS SUNDIAL

Chapter 5 described techniques for a community of nodes to agree on a common time base, appropriate for sub-millisecond measurements, but not rooted in any physical time base. Working with ArborNet suggests a somewhat whimsical approach to accurate timekeeping in an unattended network by building a "wireless sundial" from multiple embedded networking nodes.

Each node is powered entirely by solar cells, so it would only wake up when there was sun to measure. Once awake, a node would track the position of a shadow cast by a gnomon using simple photocells, and report the position of the shadow to its neighbors. Using multiple nodes would eliminate errors due to clouds, and on clear days, the network could accurately report both the solar time of day and the day of the year. The system would be guaranteed to be free of any long-term drift.

IMPLEMENT DYNAMIC DUTY CYCLE

Distributed Synchronization is a first step towards power savings. If all nodes in the network can agree on a common time base, they can all sleep at the same time and wake up simultaneously in order to exchange packets during network "business hours."

Assume that nodes draw no power while they sleep and constant power while they are awake, independent of radio activity. Let T_{wake} denote the amount of time that the they are awake and T_{sleep} the time during which they sleep, the duty cycle for the system is then:

$$T_{DC} = \frac{T_{wake}}{T_{wake} + T_{sleep}} \tag{EQ 15}$$

The system power consumed will be reduced by a factor of T_{DC} , while the load on the airwaves will be increase by the same factor.

Since many embedded network applications need only communicate to for a few milliseconds out of every minute, this approach can lead to substantial power savings.

DEVELOP MECHANISMS FOR RELOADING CODE

For all its ease in measuring and gathering data, the Embedded Networks presented here don't offer any mechanism for reloading code over the network. Part of this is due to limitations in hardware: the Constellation boards used in the ArborNet system have no provisions for dynamically reloading code. But a degree of caution influenced the design: one bad byte distributed among all the nodes could immediately bring down the network.

Nonetheless, the value in being able to dynamically reload code in order to conduct different networking tests is obvious. An embedded network system designed to dynamically update its own networking code would be an extremely useful research tool. A longer-term goal would be to create robust mechanisms for dynamically reloading code for applications outside of the laboratory.

Acknowledgements

Entering the Media Laboratory is like embarking on some strange and wonderful journey: When I started five years ago, I didn't know where it would lead me, but I had a hunch that I would have many adventures and encounter some wonderful people along the way. Time has validated my intuition, and in retrospect, I could not have scripted a better cast of characters.

My advisor, Mike Hawley, jarred me loose from my everyday life and into the Lab in the first place, and it is his ongoing vision of building smart, useful objects that has kept me happily working late nights. Committee member and sailing captain Andy Lippman has always offered good criticisms of my work, backed up with sound reasoning. Bill Kaiser, expert in the field of self-organizing networks, has always expressed enthusiasm about my work, sensibly tempering my elation by introducing me to work other people have already done in the field. I've had many stimulating talks with LCS professor Hari Balakrishnan and his students about the finer points of embedded networks—it is wonderful to have a local expert in the field. David Tennenhouse did me a great service by making me promise that I would stay focussed on completing the dissertation before being distracted by the Next Big Thing.

I have been fortunate to have been supported as a Motorola Fellow for much of my time as a Media Lab student. But the support hasn't been simply financial: I've been constantly inspired by my interactions with the engineers and managers of Motorola, and I especially appreciate Sheila Griffin's handling of the program.

I feel particularly lucky to be part of Hawley's Personal Information Architecture team. Past members Maria Redin, Manish Tuteja and John Underkoffler have remained great friends and helped me through the inevitable bumps along the road to a degree. Current colleagues Chris Newell, Roshan Baliga and especially Paul Pham have spent large blocks of their time making ArborNet into a reality, and I have come to depend upon Bill Butera for seeing technical holes that I have missed.

Two people deserve special mention, without whose help I cannot imagine this research coming to fruition. Andy Wheeler designed the Constellation board and many other elegant (though often unsung) hardware systems. Through his own example, Andy has pushed me to think harder and build more. Charlotte Burgess advanced this research in more ways than can be counted, from proofreading and graphic design to emotional and moral support. Charlotte has a talent for asking the question that unties whatever Gordian knot I am struggling with. To both Andy and Charlotte, I give special thanks.
